

THE GEOLOGY OF THE

ANGUS MINE AREA

OF THE

BARRIER RANGES,

NEW SOUTH WALES.

This thesis does not contain any material previously submitted for a degree in any University by me, or by any other person, except where due reference is made in the text of the thesis.

J. B. McMANUS 31st December, 1963

SUMMARY

The "aplites" and concordant pegmatites in the Angus area are considered to be altered sediments; the "aplites" would have been felspathic sands, or arenites with minor clay material; the concordant pegmatites are considered to be similar sediments, with greater amounts of clay material. Major soda metasomation is not invoked to explain the sodic rich nature of the rocks, which are thought to have been sodic rich sediments. Transgressive sodium rich and potassium rich pegmatites have been derived partly by pneumatolytic processes and partly by migration of ions from metasediments into joints and fractures.

The amphibolites are interpreted as having a sedimentary origin, and to have been calcareous—chloritic—siliceous—ferruginous sediments, with minor clays and sericitic material. Iron, aluminium, and magnesium metasomatism is not invoked, and the constituents of the amphibolites were originally present in the sediments. The amphibolites could also have been acidic tuffs.

All rock types have been described in detail, and the genesis of each rock type has been given.

The stratigraphic sequence and sedimentary environment could be explained by regressions and transgressions of the sea in unstable areas where uplift and subsidence occurred.

The overall structure is a limb structure, with minor folding on the limb. The beds dip steeply in a westerly direction. The overall plunge is northerly.

Metallic minerals in the area have been deposited in a calcic environment within fine-grained sediments, now gneisses, schists, calcic-plagioclase quartzites, quartz-epidote rocks, and in places, amphibolites. The mineralisation has concentrated in small folds within the calcic bearing zones. Potassic felspar associated with the mineralisation is considered to have developed partly as the result of potassium ions being relatively mobile during metamorphism and migrating to areas of lower stress, and partly by potassium ions being "repelled" from calcic environments under metamorphic conditions. A sedimentary origin is favoured for the Broken Hill type mineralisation in the area.

Vegetation-rock type associations and their possible significance have been outlined.

The results of geophysical studies have been applied to the geology.

Economic considerations have been put forward.

Surface indications of base metal mineralisation are such

that further geophysical (electrical) studies should be carried out before drilling is considered. Consideration could possibly be given to drilling at the Angus mine without further geophysical studies.

Minor beryl occurrences in some of the transgressive pegmatites within an "aplite" zone require investigation by using a Beryllium Detector (berylometer).
