1 **Editorial – Sustainable water policy must deal with risk and uncertainty**

2 Adam Loch^{1,2,3,5} and David Adamson^{1,2,3,4}

3 **Abstract**

4 This *Special Issue* of Water Economics and Policy was borne out of an interest in how the
5 research area of water resources is dealing with an increasing level of risk and uncertainty. For
6 economics and engineering, who hold some dominance in the debate, the focus appears firmly
7 set on insurance markets and robust infrastructure. These approaches have many limits, where
8 a future with little to no references to the past will provide substantial challenges for all water
9 users/managers. We find no substantial progress in the study of risk and uncertainty has taken
10 place in order to keep up with—if not ahead of—this problem. This is disappointing, but also
11 valuable if we take the warning our assessment provides and shift the focus of water
12 users/managers alike. The likelihood of that warning being heeded is unfortunately little more
13 than a pipe-dream.

16 **Acknowledgements**

17 We would like to thank the Editor for inviting us to collate this *Special Issue*, the Associate
18 Editor and the journal staff for their tireless work behind the scenes. Thank you also to the
19 many reviewers of these works without whose expertise we would not have been able to
20 progress. Finally, a huge thanks to all who contributed to the Issue and provided us with a set
21 of interesting works.

1 **Editorial – Sustainable water policy must deal with risk and uncertainty**

2 **1. Introduction**

3 As a starting point for this *Special Issue* we were reminded of an important quote from Prof
4 Richard Howitt, which underpins a fundamental problem for designing applied water policy:

5 “...*theoretical models and empirical analysis usually bog down when faced with the*
6 *three scourges of quantitative institutional analysis: nonconvexity, irreversibility, and*
7 *uncertainty*” (Howitt, 1995, pg. 1192).

8 These three issues continue to jeopardise our ability to sustainably access, supply and utilise
9 water resources from the individual to global scales. Firstly, elementary economics relies on
10 assumptions of convex supply and demand functions, sometimes using these to establish the
11 parameters for sustainable water management. In reality, water resources characterize
12 nonconvex functions providing multiple optimal solutions clouding our understanding of how
13 consumers and producers respond to the supply of and demand for water resources. Nonconvex
14 problems spell trouble for market-based policies and, as such, practical options for sustainable
15 water management. This is because an inconsistent water supply reduces the effectiveness of
16 markets, while the demand and use of the resource creates negative externalities that generate
17 new nonconvexity. Advances in nonlinear programming (NLP) and genetic/evolutionary
18 algorithms have been insightful but these solutions generally have not coupled allocation
19 changes to user behavioural responses to tease out nonconvexity issues.

20 Secondly, irreversibility poses the fundamental challenge of trade-offs and consequences from
21 actions. Irreversibility is defined as trade-offs caused by technical transformation (e.g. loss of
22 pristine natural area to dam development) where the cost of reversing that transformation is
23 prohibitive. This is known as technically irreversible development. Irreversibility can also
24 occur when: i) there is a complete failure by water users to incorporate risk into decision-

1 making, ii) there is a recognised but inaccurate perception of the true risk of water
2 supply/demand; and iii) a water user's risk-taking attitude leads to a situation where the capital
3 invested is irretrievably lost (e.g. failure to have sufficient water supply results in the death of
4 perennial rootstock).

5 Finally, uncertainty in the most extreme form (i.e. Knightian) is concerned with concepts or
6 events we are completely unaware of—and, as such, unprepared for—which will drive both
7 significant nonconvexity and irreversibility outcomes. However, in the case of water, we know
8 the resource exists so uncertainty is generally limited to an incomplete picture of its supply
9 going forward (i.e. drought or flood), water users' demand, and any adaptation to that realized
10 supply. In other words, uncertainty in water is about understanding the risk of supply and either
11 the economic consequences from failing to predict supply/demand, or how to optimally allocate
12 water resources over time to prevent an irreversible outcome. This all threatens sustainable
13 water management.

14 If you know our work, you'll know we have been thinking about water and these concepts
15 raised by Howitt for a long time. In our works we've commonly had conversations either
16 following presentations or the publication of a paper where a common assessment has been
17 that people haven't thought about risk to water resources as we explained it. This is satisfying
18 because it is nice to have a research agenda that seems original even if we are just the latest in
19 a long line of people trying to focus attention where it is needed. This is also deeply alarming
20 where evidence around us suggests the risks to water are growing, we are running out of time,
21 and the price to pay will be significant for many of us. Hence, we envisaged this *Special Issue*
22 as a means to place emphasis again on risks to sustainable water resources, and identifying
23 what work was being done by others.

24 The result was a little disheartening, but maybe not too surprising, to say the least.

1 Over the development of the *Special Issue* two factors became evident. First, while risk
2 and uncertainty are undoubtedly fundamental to understanding and managing water, we are
3 either very comfortable with the tools we have, and/or attempting to deal with a lack of
4 certainty is no longer deemed as important to manage. The second is that when we attempt to
5 work between disciplines the focus on risk is very different—principally from a supply and
6 demand point of view. While the economics literature has in some limited circles moved into
7 exploring decision-making as per adaptation at the demand level, other professions such as
8 engineering have remained focused purely on the concepts on managing risk with supply
9 measures. We will return to this later. There *is* good work being done, and water resource
10 management continues to attract intelligent people with good minds focused on our next steps.
11 Mostly that work has been on making our limited water resources—so essential for all of us
12 and our survival—sustainable into the future. Hence, our interest on sustainability as a part of
13 the focus for this *Special Issue*. However, despite our hopes, there was less focus on risk as a
14 motive for submissions. This is a major oversight, as we cannot sustainably manage a resource
15 that is likely to be fundamentally different from what we have known before. That is, the past
16 is never a very good predictor of the future. This is the base concept of risk; it is not an outcome
17 for which we have no reference or experience (e.g. uncertainty as per Knight), but rather events
18 that we can attribute probabilities to as a means of testing human, infrastructure or institutional
19 responses into the future (e.g. climate change impacts). This is usually the focus of our work
20 where we attempt to consider, represent, model and learn from water resource risks—and
21 where systems might break. It was also what we hoped others out there would be exploring.
22 But risk research as we view it, despite excellent starting points, is lacking in the economics
23 space.

24 Reasons for the lack of research in this area may be obvious. Many see risk as complex
25 and difficult to parameterize thus turning to simple concepts, representations and modelling. In

1 water while increasing research involves systems-thinking and two-way coupling between
 2 human and natural systems this approach has been used to deal with sustainability rather than
 3 issues of risk. A water sustainability focus which hinges on the fact that futures are static is
 4 nonsense, and as such the risk to our future is high and potentially irreversible. The core
 5 question within a sustainable water management framework is that, while an adaptive approach
 6 may help to keep water use at or below the sustainable threshold, will adaptation be enough
 7 when the risk of threshold change is high? For example, some estimate water demand will
 8 continue to grow in agricultural production as population and standards of living increase out
 9 to 2030—now only eight years away! They also suggest efficiency improvements (i.e. water
 10 savings) may drive higher yields from similar water consumption, but that these will likely not
 11 exceed 20%. Further, while raw water capture and storage infrastructure may result in an
 12 increase in supply via business-as-usual approaches they too may only achieve a 20% increase.
 13 The remaining gap of 60% between forecast demand and possible supply growth is a significant
 14 risk with a real probability (Figure 1), suggesting sustainable water levels or demand increases
 15 will have to be pushed lower over time. In our view risks such as this are not being considered
 16 in the literature. A good example of ignoring nonconvexity, irreversibility and uncertainty.

17 **Figure 1:** Gap between future demand and technical improvements in water supply (WRG,
 18 2009)
 19

1 Complicating this, in our view, is the fact that common solutions to water supply have
2 been investments in water-use efficiency (WUE) to ‘save’ water in one system to then allow
3 use elsewhere. Investments in WUE typically remove any perceived slack resources from a
4 system, as discussed above, and by doing so we lower a system’s capacity to cope with future
5 variation (e.g. climate change risks) because the additional resources to cope with change no
6 longer exist. Such constricted systems have a higher probability of breaking rather than flexing
7 as needed under adaptive management approaches aimed at maintaining water sustainability.
8 This puts water sustainability and risk at odds with one another, and signals future catastrophe
9 in our water systems. As such, we had hoped to see some discussion of these issues in our
10 submissions but that did not emerge and plausible solutions to future catastrophes remain
11 unknown. More than anything, an overreliance on ‘zombie’ WUE solutions in the water space
12 globally—but with limited performance with respect to environmental gains and no
13 consideration of future risk—has us extremely worried about nonconvex and irreversible
14 outcomes.

15 So, with respect to risk and its impacts on water resources, what features in the literature,
16 and how does this *Issue* contribute? In the economics discipline there is a focus on markets as
17 a method for pricing risk and spreading it across a large set of users via products such as
18 insurance. Problems with this approach occur where the scope for effective risk spreading is
19 reduced as more and more users become affected at the same time, and/or where insurance
20 suppliers determine the risk is too high ahead of an event and premium increases price many
21 outside the market. Despite the clear externality and market failure issues with insurance
22 economics, it doesn’t seem to have explored any additional set of solutions. The main driver
23 of water risk—climate change—is left to other disciplines, and adaptation at market or
24 individual levels remains a perennial research gap. Climate change is a global issue that will
25 impact a wide variety of water and human systems at basin and catchment scales through

1 vegetation loss, soil erosion, wildfire damage, tropical crop yield declines and dryland water
2 scarcity lowering agricultural production, food supply, and environmental fundamentals. These
3 risks will trigger continuous adaptation such as higher field irrigation, crop changes and farm
4 management practice shifts. This is vexing for producers and rural stakeholders struggling to
5 determine the best way to adapt in response to predictions of more frequent and severe drought
6 in 75% of years by 2050—surely a large risk in anyone’s view. Yet economics is mostly silent
7 in the water risk space.

8 The other discipline, engineering, has a focus on supply such as storages and efficiency
9 technology for agriculture. Put simply, if more water is needed, we can increase supply as we
10 have done in the past. However, as we have seen in Figure 1, there is a significant gap between
11 the expected total demand and supply potential—if we are able to address considerable
12 environmental and business-case concerns surrounding supply augmentation. Like WUE,
13 many of those set to gain from rent seeking (e.g. farmers, construction companies, regulators,
14 irrigation suppliers) favour such public investment, but none of them will typically be required
15 to pay the costs of building, operating and maintaining the infrastructure. These costs can be
16 significant over time, and the small rates of return recovered will go nowhere close to what it
17 actually costs in full. Engineers do consider risks to these structures using robust analysis of
18 their exposure longer-term, as storages may last 150 years or more in the landscape (i.e. an
19 example of technically irreversible development). However, the adaptation potential by such
20 structures to the impacts of climate change does not seem to be considered more widely with
21 respect to water where, for example, in future rainfall may occur nowhere near the catchment
22 for a dam making it redundant. Further, any focus on WUE typically tends to reduce flexibility
23 in the water system—to say nothing about the human component—with a focus on mean and
24 variance as signals of relevant risk; but which also downplays the fact that the human part of
25 water systems adapt quite regularly and in ways likely not seen before.

1 In our view, neither of these disciplines is doing much to help us focus on the risks
2 associated with water resources, where the future will be very different from what we have
3 experienced to date. In particular, neither is helping to identify real solutions to the 60% gap
4 between demand and supply out to 2030 as an alternative to common storage/WUE technology
5 strategies which are already failing globally. We have already had plenty of arguments with
6 engineers who simply do not see that WUE has limitations or that there is anything wrong with
7 robust analysis that does not take human behavioural change into account. In a future
8 dominated by water-human systems thinking this will become an issue for solution discovery.
9 But often the political nature of water resources, where they remain publicly-owned and
10 regulated, tends to position short-term political gains over longer-term practical solutions with
11 higher total costs monetarily, socially and environmentally. There is little reason to expect or
12 rely on changes to the politics of water management globally until the risks have become real,
13 but now far harder and more expensive to adapt to.

14 **2. Overview of Papers in the Issue**

15 **2.1. “*Environmental regulation and economic development: Evidence from the River* 16 *Chief System in China*” by Liu and Bai**

17 The authors apply robustness tests on a series of bottom-up regulations aimed at addressing
18 pollution—where in other disciplines (e.g. engineering) robustness tests are aimed at the
19 management of risk. They then join this to a sustainable objective of balancing economic
20 development with environmental protection via structural upgrades (which are similar to WUE
21 products) and other technological innovations. The authors seem to correctly observe that
22 regulation for environmental gains does not rule out economic progress. But the robustness
23 tests apply backward-looking data to inform how things will pan out in future, which is not
24 really an accurate assessment of what we would term risk. This is mainly demonstrated by the
25 regression modelling and its reliance on historic data, as well as the failure to assess how the
26 gap between demand and supply levels undermines any reliance on technology and structural

1 innovation. So, while we appreciate what the authors have written from an informative
2 economics and engineering perspective the risk problem as we have described above continues.
3 This is an interesting difference not appreciated by both disciplines, nor explored much in the
4 literature.

5 **2.2. “Optimizing Long-Term Irrigation of Areas above an Unconfined Aquifer: Quantity
6 and Quality Considerations” by Simsa**

7 As a useful contrast, the human element with respect to water planning and decision-making is
8 covered by this paper. Using Israeli water use as a case study the author argues that any absence
9 of longer-term planning may lead to deteriorated water assets and the high probability
10 (irreversible risk) of shutdown or failure. A solution may arise from optimal planning (convex
11 solutions), regulation and spatial location of groundwater pumping stations as part of the total
12 consumptive supply mix which may enable exploration of the economic and environmental
13 management objectives to meet sustainability issues. But again, the perspective is backward-
14 looking—and free of nonconvex outcomes—and so not necessarily incorporating threshold
15 issues never previously experienced. Importantly, the work shows that while changed
16 economic and water-supply conditions alter decisions in sensitivity analysis Simsa fails to
17 achieve the research objective of identifying an optimal state path toward a steady-state
18 equilibrium using current (i.e. historical) aquifer data. However, the author concludes that
19 substantial (i.e. Knightian) uncertainties affect steady-state outcomes—among other things in
20 complex water management—requiring a focus on future risk.

21 **2.3. “Local Communities’ Willingness to Contribute Toward the Improved Water Quality
22 of the River Yamuna” by Tandon and Das**

23 In a similar issue of water quality from India, the authors explore the important contribution of
24 community or public engagement with pollution programs. Using a contingent valuation
25 method they determine what incentives may work among more receptive groups (e.g. younger
26 women) to encourage participation and improvement. The issue again remains one of risk,
27 where past data informs future choices, and a key lack of public enforcement. As observed in

1 this paper, a lack of trust in governments to do the right things may limit engagement with
2 certain programs, while smaller community or personal arrangements trying to meet health,
3 food or habitat may appeal more. As such, while ever the future risk of water pollution and
4 health issues remains high, localized participation may offer a way forward but only where the
5 scale and impact of those risks are made clear; which does not seem to be the case in the paper.
6 This makes individual choices more difficult to model, and risk becomes another casualty of
7 the analysis approaches.

8 **2.4. “Overcoming deterministic limits to robustness tests of decision-making**
9 **given incomplete information: the state contingent analysis approach” by**
10 **Adamson and Loch**

11 To explore the issue of analysis and its implications for policy/program decisions the authors
12 explore the nature of human decision-making in water resource uses, with a focus on learning
13 as an example of how risk may feature in an individual’s experiences with water resources to
14 then inform and alter future choices, planning and investments. This may seem simple enough,
15 but it is surprisingly absent from much of the literature apart from water-human systems
16 thinking. To address this they examine expected-value (EV) models that are commonly, and
17 rightly, used around engineering projects; but argue they have little to no value in human
18 systems. In such cases, state contingent analysis (SCA) modelling which can accommodate
19 tail-end scenarios within shifting probability distributions may offer superior analysis
20 outcomes. In the paper risk associated with future climate change employs little to no reference
21 to backward-looking conditions, making any use of mean/variance data particularly pointless,
22 and highlighting the value of scenarios as a means of testing robustness in human systems.

23 **2.5. “A Hydro-economic Model to Calculate the Resource Costs of Agricultural**
24 **Water Use and the Economic and Environmental Impacts of their Recovery”**
25 **by Sapino, Pérez-Blanco and Saiz-Santiago**

26 Finally, the economic and environmental interests in access to water resources remains a
27 popular research topic, especially from a sustainability perspective. In their paper, the authors

1 utilise two separate models: a hydrological model and an economic optimization model to
2 explore environmental water recovery options from determining the true water supply cost. It
3 has long been argued that full cost recovery provides the necessary conditions for a sustainable
4 level of water use to be determined, so this paper thus explores the literature debate concerning
5 the winners and losers from full cost recovery. Such a strategy provides the capacity to bring
6 the best models together to be used in an iterative way, and then into a well-developed and
7 respected economic model. Subsequent work should be aimed at progressing towards merging
8 the models so they solve simultaneously and not sequentially which would offer a range of
9 advancements to explore risk and sustainable water policy settings by the internalization of
10 nonconvex supply/demand issues to minimize irreversible losses.

11 **3. Synthesis and Policy Implications**

12 One of the major lessons that comes out of this examination of water sustainability and (to a
13 lesser degree) the problems of increasing risk is that governance, management and academic
14 study of water and its problems is critical for adaptation and furthering resource use/access;
15 but none of these institutions is applying themselves as they should. A major problem of
16 addressing water shortages, demand increases and supply limitations/costs is that eventually
17 the human-water systems will snap. With respect to water resources risk neither economics or
18 engineering have progressed very far in recent decades, and politics is clearly going backward
19 under increasing challenges of declining trust, perceptions of incompetence, or limited social
20 license for relevant commercial entities. Generally, there is much to do but no real reason to be
21 held accountable. This may be acceptable for issues other than water, but as we can't live
22 without it the importance of water supply and management is life-threatening. Globally we
23 need to find the means and incentives to change this situation.

24 Further, WUE won't save us by providing increased supply—the need is for alternative
25 solutions that present ideas outside the box. And if we think insurance will cover the losses as

1 advocated by economic theory the answer is also no. For example, as climate change impacts
2 and risks shift there are parts of Australia which no longer attract insurance cover (e.g. northern
3 Queensland above the Tropic of Capricorn which may no longer be eligible for policy exposure
4 or assessment). If we are unable to identify reasonable ideas to deal with this demand/supply
5 risk the sustainability of human, ecological and other species needs for water resources remains
6 perilous. We may need to think about the suspension or outright cancellation of some water
7 rights to limit exposure to risk, and investing (substantial) transaction/abatement costs to
8 establish new studies and inducements to change behaviour. And given the difference between
9 future data outcomes those scenarios should be represented using 'new' futures based on
10 historical data but with clear exploration of tails in distributions.

11 Ultimately, the risks associated with tail events and the changing probability of
12 variations/impacts should be well studied, understood and factored into planning, reform and
13 adaptation options going forward. The future risk of water shortages is quite prominent which,
14 as we've shown, is not present in most papers of the *Issue*. The past is always comforting to
15 researchers/users as a basis for calibrating base lines and then building scenarios. But what
16 happens if the future has no correspondence with (local) base lines? Robustness tests have very
17 different perspectives and bases for setup, representation and test-objectives. This must be
18 explored more, and separated across humans/infrastructure. We argue there is much economists
19 and engineers can learn from one another, but some in the engineering discipline appear fixated
20 on augmenting water supply only. This has been disappointing, but there is scope for change if
21 we extend invitations to work together in future. Economics also has much to learn about how
22 to do risk assessments differently, to improve risk assessment beyond insurance market
23 solutions given expected future change. The opportunity in this area appears rich for
24 collaboration on needed answers.

1 Finally, climate change will lead to longer and more severe droughts that may only be
2 interrupted by more intense and destructive floods with significant negative impacts. Policy-
3 makers must deal with these vagaries in water demand and supply, but again we see little to no
4 evidence of that in their behaviour. This is unsurprising where water agency understanding of
5 how to manage the conjunctive resource (i.e. groundwater, surface water, wastewater and
6 transfers), both in terms of the quantity of the resource available and the quality of that resource,
7 is becoming increasingly complex. It would be nice if risk probability as an entry-point to
8 analysis via scenarios, human investment or other decision-making, valuing seasonal climate
9 forecasts, adaptation choices and outcomes, or policy evaluation were used to properly frame
10 and represent complex water issues. Until wider applications occur we will remain ignorant of
11 the nonconvex outcomes, irreversible costs, possible alternatives to business-as-usual and
12 solutions beyond water markets, the limits of WUE, and the need for flexible water
13 management options in response to climate impacts.

14 We think this *Special Issue* may have failed to address the problem. So, the challenge is
15 back on the reader, and researchers more widely, to help find solutions.
