

"D<sub>3</sub> CHROMOPHORES -  
geometric distortion in trigonal-dihedral transition metal  
chromophores and its relevance to optical circular dichroism."

a thesis submitted for the  
Degree of Doctor of Philosophy  
at the University of Adelaide  
in May, 1973.

by KEITH RAYMOND BUTLER, B.Sc. (Hons.)

Department of Physical and Inorganic Chemistry.

SUMMARY

The crystal structures of the inorganic salts, sodium (+)<sub>546</sub>-bis(malonato)1,2-diaminoethane cobaltate(III) dihydrate, Na (+)<sub>546</sub>[Co(C<sub>3</sub>H<sub>2</sub>O<sub>4</sub>)<sub>2</sub>(C<sub>2</sub>H<sub>8</sub>N<sub>2</sub>)]·2H<sub>2</sub>O, (-)<sub>589</sub>-tris((-)<sub>589</sub>1,2-diaminopropane)cobalt(III) (+)<sub>589</sub>-tris(malonato)chromate(III) trihydrate, (-)<sub>589</sub>[Co(-)<sub>589</sub>(C<sub>3</sub>H<sub>10</sub>N<sub>2</sub>)<sub>3</sub>](+)<sub>589</sub>[Cr(C<sub>3</sub>H<sub>2</sub>O<sub>4</sub>)<sub>3</sub>]·3H<sub>2</sub>O, and potassium calcium (+)<sub>589</sub>-tris(dithiooxalato)cobaltate(III) tetrahydrate, K.Ca (+)<sub>589</sub>[Co(C<sub>2</sub>O<sub>2</sub>S<sub>2</sub>)<sub>3</sub>]·4H<sub>2</sub>O, have been determined and refined by a full-matrix least-squares procedure with conventional *R* factors at convergence of 0.050, 0.073 and 0.062 respectively. The absolute configurations of the complex anions in the respective structures were assigned as Δ, Λ and Λ.

The absolute configurations of the complex ions in the previously determined structure, potassium (+)<sub>589</sub>-tris(1,10-phenanthroline)nickel(II) (-)<sub>589</sub>-tris(oxalato)cobaltate(III) dihydrate, K(+)<sub>589</sub>[Ni(C<sub>12</sub>H<sub>8</sub>N<sub>2</sub>)<sub>3</sub>](-)<sub>589</sub>[Co(C<sub>2</sub>O<sub>4</sub>)<sub>3</sub>]·2H<sub>2</sub>O, have both been determined as Λ using the technique of X-ray anomalous dispersion. The complex ions (+)<sub>589</sub>-tris(oxalato)chromate(III), (+)<sub>589</sub>[Cr(C<sub>2</sub>O<sub>4</sub>)<sub>3</sub>]<sup>3-</sup>, (-)<sub>600</sub>-tris(malonato)cobaltate(III), (-)<sub>600</sub>[Co(C<sub>3</sub>H<sub>2</sub>O<sub>4</sub>)<sub>3</sub>]<sup>3-</sup>, (-)<sub>400</sub>-tris(1,3-diaminopropane)chromium(III), (-)<sub>400</sub>[Cr(C<sub>3</sub>H<sub>10</sub>N<sub>2</sub>)<sub>3</sub>]<sup>3+</sup> and (+)<sub>589</sub>-tris(1,10-phenanthroline)ruthenium(II), (+)<sub>589</sub>[Ru(C<sub>12</sub>H<sub>8</sub>N<sub>2</sub>)<sub>3</sub>]<sup>2+</sup>, have all been assigned a Λ absolute configuration on the basis of X-ray powder diffraction patterns of the relevant least-soluble diastereoisomers.

Angular distortion parameters of the  $ML_6$  coordination polyhedra in several inorganic structures of pseudo- $D_3$  symmetry have been computed from the crystal coordinates; the distortion of this core from  $O_h$  symmetry in tris-bidentate complexes has been correlated with the size of the ligand bite angle,  $\alpha$ , on the basis of a repulsive electrostatic potential operative between the six ligand donor atoms. This theoretical model predicts a distortion towards trigonal-prismatic geometry for tris-complexes containing bidentate ligands which subtend angles,  $\alpha$ , less than  $90^\circ$  at the coordinated metal atom; for  $\alpha > 90^\circ$  the model predicts a geometry more flattened relative to the three-fold axis than that in which the three bidentate ligands are orthogonal.

The computed  $ML_6$ -core distortions of relevant tris-bidentate transition metal complexes have been considered in assessing the validity of a limited crystal-field trigonal distortion model proposed by Piper and Karipides for correlating the absolute configuration of a chiral trigonal-dihedral ( $D_3$ ) chromophore with the sign of the observed rotatory strength. It is concluded that this model does not adequately explain the observed Cotton effects for all pseudo- $D_3$  transition metal complexes.

DECLARATION

This thesis is an account of research conducted by the candidate in the Department of Physical and Inorganic Chemistry at The University of Adelaide, the School of Physical Sciences at The Flinders University of South Australia and through the agency of my supervisor, Dr. M.R. Snow, in the Department of Chemistry at Northwestern University, Illinois, U.S.A.

The thesis contains no work previously presented by the candidate for the award of any other degree and to the best of the author's knowledge includes no material written by another person, except where due reference is made in the text of the thesis.

Responsibility for any factual or typographical errors present in the text rests solely with the author.

Keith Butler,  
May, 1973.

ACKNOWLEDGEMENTS

I express sincere thanks to my supervisor, Dr. M.R. Snow, for his interest and encouragement throughout the duration of this research and particularly for his willingness to determine numerous circular dichroism spectra on my behalf while on study leave.

Special thanks are due to Dr. M.R. Taylor of Flinders University for making available the diffractometer facilities used in one crystal data collection and together with Miss L. Srinivasan for helpful discussions on the refinement and absorption correction of counter data; to Dr. M. Dwyer for discussions on structure solution and refinement; to Dr. S.F. Lincoln for assistance in understanding the implications of several relevant nmr studies and to Dr. G.H. Searle for many informative discussions on optical activity. I also thank Drs. B.F. Hoskins and K. Matsumoto, and Professors W.D. Horrocks, Jr., and Y. Saito for crystal structure coordinates in advance of publication.

In particular thanks are due to some fellow students; to Mr. P.F. Crossing and Mr. R.J. Geue for providing the coordinates from the energy minimization studies of the tris-diamine and bis-triamine complexes and to Messrs. F.R. Keene, T.R. Norman and G.J. Sparrow for help with optical rotatory dispersion and spectral measurements. Messrs. A. Bowers, G. Duthie and B. Weste gave much assistance in the design and modification of an automatic low temperature device for use with the Weissenberg camera.

I thank Professors D.O. Jordan and D.R. Stranks for allowing me to

undertake this research in the Department of Physical and Inorganic Chemistry and the Department of Education and Science for granting me a Commonwealth Postgraduate Award for the duration of this study. Finally I wish to acknowledge use of the facilities of the University of Adelaide's Computing Centre.

1.

## INTRODUCTION

At present the only definitive ways of assigning the absolute configurations of metal complexes are chemical relation to a compound of known chirality (*Gk.*  $\chi\epsilon\iota\rho \equiv \text{chir} - \equiv \text{hand}$ ), e.g. complexes of  $(-)\text{pn}^{\dagger 1}$  derivatives,<sup>1-3</sup> and X-ray structure solution employing the property of X-ray anomalous dispersion,<sup>4-6</sup> the latter being the only "direct" method. Earlier in the study of optical activity in transition metal complexes it was thought<sup>7</sup> that their absolute configurations could be deduced from the sign of the rotation of plane polarized light at a fixed reference wavelength. However, it had previously been observed that the optical rotatory dispersion (ORD) curves for chiral molecules exhibited an inflexion point and generally changed sign under an absorption band,<sup>8,9</sup> making predictions based on the sign of the optical rotation at fixed wavelength doubtful. It was subsequently shown theoretically that the sign of the observed Cotton effect (see terminology section, part (2)) for an isolated optically active transition was determined by the chromophore absolute configuration.<sup>10,11</sup> The finite extension of the rotatory dispersion beyond the limits of the absorption band envelope leads to a complicated ORD curve which is not readily resolvable into separate dispersions for chromophores having several optically active transitions in a narrow wavelength range.

It is currently held that the absolute configurations of chiral chromophores should most readily correlate with the features of the circular

---

<sup>†1</sup> ligand abbreviations and structural formulae are given in the terminology section, part (3), immediately following this introduction.

2.

dichroism (CD) spectra, since for an isolated transition the CD peak is confined within the envelope of the absorption band, although a small shift to low energy relative to the frequency of the absorption maximum is predicted.<sup>12,13</sup> Transitions which give overlapping ORD curves should be more clearly resolved in the corresponding CD spectrum.

Despite the fact that the Cotton effect in CD was first observed for an inorganic system,<sup>14-17</sup> the development of widely applicable theoretical models lags behind the theoretical interpretation of the phenomenon in organic chemistry.<sup>18-20</sup> This is partly a consequence of the differences in the electronic transitions being studied, and in the inorganic sphere theory best describes the experimental facts for the  $\pi \rightarrow \pi^*$  transitions of unsaturated ligands such as 1,10-phenanthroline and 2,2'-dipyridyl when chelated to transition metal ions.<sup>21-24</sup> Analogous  $n \rightarrow \pi^*$  and  $\pi \rightarrow \pi^*$  transitions are the most studied in organic compounds containing, for example, the carbonyl chromophore. For transition metal complexes containing saturated ligands, such as the aliphatic diamines, the transitions most studied have been the low intensity, spin-allowed  $d-d$  transitions centred on the metal ion and generally observable in the visible spectral region. The theoretical treatment applicable to the  $\pi \rightarrow \pi^*$  ligand transitions of phen and dipy complexes cannot be used in these cases.

The precise details of the ORD and CD spectra of a transition metal complex are related to its symmetry, the spectroscopic interpretation being least complex for ions of high symmetry. The highest symmetry

3.

transition metal complexes capable of existing in two non-superimposable mirror image forms (enantiomers) have trigonal-dihedral ( $D_3$ ) symmetry, e.g.  $\text{Co(en)}_3^{3+}$ ,  $\text{Co(ox)}_3^{3-}$ ,  $\text{Ni(phen)}_3^{2+}$ , and it is these which have been studied most extensively theoretically.<sup>25</sup> Aware of the relevance of  $D_3$  complex ions to the empirical CD correlations we had, in 1968, initiated determination of the crystal structure of  $\text{K(+) }_{589}[\text{Ni phen}_3](-)_{589}[\text{Co ox}_3].2\text{H}_2\text{O}$  by X-ray diffraction, work which fulfilled the experimental requirements of the author's Honours Degree for that year. Assignment of the absolute configuration was completed in 1969 and when published (K.R. Butler and M.R. Snow, J. Chem. Soc. (A), 565 (1971)) constituted the first publication of a structure determination of the absolute configuration of a tris(oxalate) ion and the second of a tris(phenanthroline) complex, an earlier publication<sup>26</sup> of the structure of  $\Lambda(-)_{589}[\text{Fe phen}_3](+) \text{Sb}_2(\text{C}_4\text{H}_2\text{O}_6).8\text{H}_2\text{O}$  being in abstract form only.

Our interest in conformational analysis of inorganic molecules prompted consideration of complexes containing six-membered chelate rings and the tris(malonate) ion presented itself as a logical extension of the tris(oxalate) study, particularly since some anomalies seemed to exist in the published CD<sup>27,28</sup> and spectral assignments.<sup>29</sup> As a complement to the proposed tris(malonate) study, solution of the crystal structure of  $\text{Na (+)}_{546}[\text{Co mal}_2\text{en}].2\text{H}_2\text{O}$  was undertaken in 1969; crystals of this complex were readily available, the CD spectrum had been published<sup>30</sup> and the complex ion offered a link in the chain of an

## 4.

empirical correlation of the absolute configurations of the tris(<sup>en</sup>ox) and tris(mal) ions. In addition, no X-ray studies of coordinated malonate ions had been reported and although nmr spectra of  $\text{Co}(\text{mal})_2(\text{en})^-$  had previously been studied in detail<sup>31,32</sup> the conformations of the malonate rings could not be determined.

Crystallization and subsequent resolution of  $\text{K}_3[\text{Cr mal}_3]$  proved difficult and delayed data collection for  $(-)_589[\text{Co}(-)\text{pn}_3](+)_589[\text{Cr mal}_3] \cdot 3\text{H}_2\text{O}$  until mid 1970. It was about this time that the crystal structure<sup>33</sup> of  $(+)_546 \text{Co}[\text{TRI}_2]\text{I}_3$  came to our notice; the optical activity of this bis-tridentate complex ion was attributed<sup>33</sup> to a chiral twist of the nitrogen donor atoms comprising the first coordination sphere, after a model proposed by Piper and Karipides.<sup>34,35</sup> The tris(malonate) complex promised a further test of this theoretical model. A published reassignment<sup>36</sup> of the components in the CD spectrum of  $\text{Co}(\text{tn})_3^{3+}$  which appeared shortly after was also claimed to support the Piper-Karipides trigonal-distortion model and increased our interest in the detailed theory. We subsequently published an interpretation of the experimental  $[\text{Co tn}_3]^{3+}$  data available at that time (K.R. Butler and M.R. Snow, *Inorg. Chem.*, 10, 1838 (1971)).

An accurate structure determination of the geometry of the  $[\text{Co tn}_3]^{3+}$  complex ion in the crystal environment used for the experimental CD measurements was clearly required but rapid deterioration<sup>37</sup> of the crystals made this impossible by photographic techniques. Preparation of the related tris-(2,4-diaminopentanediamine)Co(III) complexes was

begun with a view to determining the absolute configurations and detailed geometries of these conformationally rigid ions, only to find in a publication<sup>38</sup> some months later that the complexes had been resolved and X-ray structure determinations were in progress.<sup>39,40</sup>

Reversal of CD component energies under the long wavelength absorption band in the published spectra<sup>27</sup> of  $[\text{Co ox}_3]^{3-}$  and  $[\text{Co thiox}_3]^{3-}$  pointed to a probable axial elongation of the  $\text{CoS}_6$  core in the latter complex ion relative to that of the  $\text{CoO}_6$  core in the  $[\text{Co ox}_3]^{3-}$ . A less than satisfactory conclusion to the refinement of the  $(-)[\text{Co}(-)\text{pn}_3](+)[\text{Cr mal}_3].3\text{H}_2\text{O}$  structure prompted the collection of extensive diffractometer data for the  $\text{K.Ca } (+)_{589}[\text{Co thiox}_3].4\text{H}_2\text{O}$  structure. Richardson's theoretical paper<sup>41</sup> extending the original trigonal distortion model of Piper and Karipides to second order appeared in mid-1971; this paper suggested a further variation of the crystal field model which the tris(thiox) ion seemed eminently suited to test. A preliminary communication of the structure has been published (K.R. Butler and M.R. Snow, *Inorg. Nucl. Chem. Letters*, 8, 541 (1972)) as has a brief account of the two malonate complex ion structures (K.R. Butler and M.R. Snow, *Chem. Comm.*, 550 (1971)).

However, the absolute configurations determined during the course of the present research do not constitute a sufficiently broad base for testing the model proposed by Piper and Karipides. It has therefore been necessary to abstract other relevant structures from the published literature and, since the parameters defining the deviation of the  $\text{ML}_6$  first coordination sphere from regular  $\text{O}_h$  symmetry are seldom listed

in structure reports of tris-bidentate complexes, a program was written to derive the required parameters from the crystal coordinates. Development of this program facilitated the evaluation of the  $ML_6$ -core distortion parameters for numerous trigonal-dihedral ( $D_3$ ) structures which, although not all of immediate relevance to an evaluation of the trigonal distortion model, are of considerable structural and in some cases spectral interest.

This accumulation of structural data for a variety of tris-bidentates revealed a tendency for the three chelate-rings in many such complexes to adopt an orientation more nearly parallel to the pseudo three-fold axis than is the case for an orthogonal arrangement of the ligands. The observed distortion has been interpreted in terms of an electrostatic repulsion potential operative between the donor atoms of the  $ML_6$ -core, and its implications with respect to the trigonal twist inversion mechanism proposed for the intramolecular racemization of  $C_3$  symmetric complexes discussed. Kepert<sup>42</sup> has recently published a similar analysis of the distortion of the  $ML_6$ -core in tris-bidentate complexes; the predictions of his independent treatment are in complete accord with those of the present work.

In presenting this research it has proved expedient to nominally divide the thesis into two parts. These introductory remarks are followed by a brief section of terminology used in the text of the thesis. Then — PART I, comprising the experimental sections: Chapters 1-5.

While the bulk of the experimental work undertaken during this

## 7.

research has been the solution of three crystal structures, some relevant rotatory dispersion and circular dichroism measurements have been made, these being summarised in Chapter 5.

PART II, comprising the analysis of chromophore geometries: Chapters 6-8.

Chapter 6 reviews the interpretation of the spectral theory of transition metal complexes adopted throughout this thesis.

The trigonal distortion model is elaborated in Chapter 7.

The derived geometrical parameters of several pseudo trigonal-dihedral ( $D_3$ ) transition metal complexes are presented and discussed in the concluding chapter.

### RELEVANT TERMINOLOGY

#### (1) Crystal Structure Refinement

The method of least-squares was used to refine the initial parameters,  $p_i$ , approximating the structure solution. The function minimized by program FUORFLS (see Appendix I) is

$$D = \sum_{hkl} w_{hkl} \Delta^2 \quad \text{where } \Delta = ||F_o| - |F_c||$$

and  $w$  is the weight assigned to the observed structure factor amplitude  $|F_o|$  (Appendices II, III);  $|F_c|$  is the scaled calculated structure factor amplitude of reflection  $hkl$ .

Since the "normal equations"

$$\sum_{hkl} w_{hkl} \Delta \frac{\partial F_c}{\partial p_i} = 0 \quad i = 1, \dots, m$$

are non-linear, minimization of  $D$  is an iterative procedure, each cycle

8.

resulting in improved values of the variables,  $p_i$ , which must be reintroduced to subsequent refinement cycles. The refineable variables are the scale factor, an extinction parameter (not refined in the structures reported here), the atomic positional coordinates  $x_i, y_i, z_i$ , an atomic occupancy factor (multiplier) and temperature factor(s): the multiplier and temperature factor(s) of a given atom may not be refined during the same least-squares cycle. For an anisotropically vibrating atom the isotropic temperature factor coefficient,  $B_i$  ( $\text{\AA}^2$ ), is replaced by the six coefficients

$$\beta_{11} = a^2 \cdot B/4, \quad \beta_{22} = b^2 \cdot B/4, \quad \beta_{33} = c^2 \cdot B/4$$

$$\beta_{12} = a \cdot b \cdot \cos \gamma \cdot B/4, \quad \beta_{13} = a \cdot c \cdot \cos \beta \cdot B/4, \quad \beta_{23} = b \cdot c \cdot \cos \alpha \cdot B/4$$

and the atomic scattering factor is given by

$$f = f_0 \exp\{-(h^2 \beta_{11} + k^2 \beta_{22} + l^2 \beta_{33} + 2hk \beta_{12} + 2hl \beta_{13} + 2kl \beta_{23})\},$$

$f_0$  being the scattering factor for the atom at rest. There are precise relationships restricting the independence of the six anisotropic temperature coefficients for an atom occupying a crystallographic special position.<sup>54</sup>

$$B_i = 8\pi^2 \overline{\mu^2}$$

where  $\overline{\mu^2}$  is the mean-square amplitude of vibration.

After a least-squares cycle the temperature factor coefficients for each atom are tested for positive-definite form; non "positive-definiteness" signifies a physically unreal thermal ellipsoid.

Improvement in the reflection-by-reflection agreement between

$|F_o|$  and  $|F_c|$  with successive least-squares cycles is indicated by the residual index

$$R_1 = \Sigma |\Delta| / \Sigma |F_o|.$$

Meaningful changes in  $R_1$  as a result of altering the model can be distinguished<sup>55</sup> by a comparison of the values of the weighted residual,  $R_2$ , before and after the current cycle;

$$R_2 = (\Sigma w \Delta^2 / \Sigma |F_o|^2)^{\frac{1}{2}}.$$

A further indicator of the refinement progress is the standard error,  $G$ , of an observation of unit weight; this is ideally unity for a properly weighted model (i.e. where  $w_{hkl} = 1/\sigma_{F_o}^2$  on an absolute scale) if random experimental errors only are significant:<sup>44a</sup>

$$G = (D/(m - n))^{\frac{1}{2}}$$

where  $(m - n)$  is the excess of independent reflections over variable parameters.

The estimated standard deviation (esd),  $\sigma_{p_i}$ , associated with a refined parameter is output, thus permitting a meaningful evaluation of the shift magnitudes of the variable parameters;

$$\sigma_{p_i} = G \cdot \sqrt{b_{ii}}$$

where  $b_{ii}$  is the  $i^{th}$  diagonal element of the inverse matrix used in solving the normal equations.  $\sigma_{p_i}$  is inversely proportional to the square root of the number of reflections included in the least-squares cycle and directly proportional to their standard deviations,  $\sigma_{F_o}$ .

In addition to outputting the above parameters and refinement

indicators program FUORFLS lists  $R_1$  and  $R_2$  in ranges of  $(\sin\theta)/\lambda$  and average  $w\Delta^2$  ( $\equiv Av. w\Delta^2$ ) against max.  $|F_o|$  for the data in specified intensity ranges. These distributions serve to indicate intensity outliers and the suitability of the chosen weighting scheme, which is important in deriving the correct standard deviations of the variable parameters.<sup>44a</sup> For correctly weighted data  $Av. w\Delta^2$  should be constant in ranges of fifty or more reflections against both max.  $|F_o|$  and  $(\sin\theta)/\lambda$  provided the model is complete; neglect of hydrogen atoms or incomplete anisotropic refinement can disturb the distribution.<sup>44a</sup>

Finally, in comparing structural parameters derived by full-matrix least-squares refinement of X-ray crystallographic data it should be remembered that the derived standard deviations have been shown<sup>52,56</sup> to be too optimistic by a factor of about two.

(2) Optical Rotatory Dispersion and Circular Dichroism

The electromagnetic radiation known as visible light spans a wavelength ( $\lambda$ ) range of ca. 330-780 nm, corresponding to a frequency ( $\nu$ ) distribution of ca. 30,000-13,000  $\text{cm}^{-1}$ . In monochromatic light the electric field ( $\underline{E}$ ) oscillates with fixed frequency perpendicular to the

direction of propagation; the magnetic field vector ( $\underline{H}$ ) oscillates orthogonal to both  $\underline{E}$  and the direction of propagation.

The electric vector of monochromatic light can be viewed as the resultant of an orthogonal  $x$  and  $y$  component oscillating perpendicular to the axis of propagation; for a phase difference of  $n\pi$  ( $n$  integral) <sup>linear</sup> the resultant is a straight line and the light is said to be linearly (or plane) polarized. When the orthogonal vibrations are out of phase the electric field vector traces an ellipse, i.e. the light is elliptically polarized. In the special case of equal components having phase difference  $\pi/2$  the light is circularly polarized; plane polarized light can be physically separated into a right- and left-circularly polarized beam (phase difference  $+$  or  $-\pi/2$ ).

A chromophore, i.e. colour centre having a transition in the wavelength range of interest, absorbs the monochromatic radiation of frequency corresponding to the transition energy. For an electric-dipole allowed one-electron transition  $a \rightarrow b$ <sup>†1</sup> the magnetic-dipole and electric-quadrupole intensity is sufficiently small to be neglected and to a good approximation the transition strength is given by

$$D_{ba} = |(a|\mathcal{V}_e|b)|^2 = \rho^2$$

where  $\mathcal{V}_e$  is the electric-dipole moment operator

and  $\rho$  the electric-dipole moment.

---

<sup>†1</sup> Throughout this work absorption transitions are written  $a \rightarrow b$  from ground state  $a$  to excited state  $b$ ; the more usual representation is  $b \leftarrow a$ .

The dipole strength,  $D_{ba}$ , of the transition can be empirically determined<sup>57</sup> from the area of the unpolarized absorption band as

$$D_{ba} = \frac{3hc}{8\pi^3 N_1} \int_0^{\infty} \frac{\epsilon}{\nu} d\nu \quad \text{c.g.s. units}$$

where  $h$  = Planck's constant,

$c$  = the velocity of light,

$N_1$  = the number of molecules per  $\text{cm}^3$ ,

and  $\epsilon$  is the decadic molar extinction coefficient.

The spin-allowed transitions of metal complexes give absorption bands of finite width (rather than the sharp lines of atomic spectra) due to the vibrational modes of the chromophore.

Chromophores lacking a rotary inversion axis<sup>58,59</sup> can exist in two non-superimposable mirror image forms; they are termed *chiral*. Where racemization is not too rapid chiral molecules can be separated into two enantiomers (or antipodes) which have identical chemical and physical properties apart from their interaction with other chiral molecules or polarized light. Because of their ability to rotate the plane of polarization of plane polarized light they are said to be *optically active*. The specific rotatory power,  $[\alpha]_{\lambda}^t$ , of a compound in a specified environment is constant for a fixed wavelength, being positive for one enantiomer and negative for the other (or zero for both); the enantiomers referenced in this work are designated (+) or (-), being dextro- or laevo-rotatory at the  $\text{Na}_D$  line ( $\lambda = 589 \text{ nm}$ ) unless an alternative reference wavelength is specified.

The variation of  $[\alpha]_{\lambda}^t$  with wavelength is termed *optical rotatory dispersion*, ORD. The observed rotation,  $\alpha$ , results from the different refractive indices ( $n_l, n_r$ ) for left- and right-circularly polarized light in a chiral chromophore and the variation of  $[\alpha]$  follows the dispersion of refractive index with wavelength;<sup>9</sup>

$$\alpha = \pi(n_l - n_r)/\lambda$$

For an isolated optically active transition  $[\alpha]$  changes sign at the wavelength of the absorption maximum ( $\lambda_{max}$ ) tailing asymptotically to zero outside of the absorption band envelope,<sup>11,17</sup> as represented by Drude's equation;<sup>8</sup>

$$[\alpha] = \frac{A}{(\lambda^2 - \lambda_{max}^2)}$$

where  $A$  is a constant for a particular system.

In some practical cases an inflexion only is observed without sign change, e.g.  $[\text{Co tn}_3]^{3+}$ , (ref. 60).

Optically active molecules absorb left- and right- circularly polarized light to different extents; the difference ( $\epsilon_l - \epsilon_r$ ), where  $\epsilon_l, \epsilon_r$  are the decadic molar extinction coefficients for left and right circularly polarized light, is called *optical circular dichroism*, CD. The ORD curve is the differential of the CD spectrum with respect to frequency; together they comprise the *Cotton Effect*.<sup>17,61</sup> A positive Cotton effect is defined as one in which the ORD passes through a maximum and then a minimum as the frequency increases; this corresponds to a positive CD peak ( $\epsilon_l > \epsilon_r$ ) centred at the absorption maximum (see

Figure A.1). If the (+)enantiomer exhibits a positive Cotton effect that of the (-)enantiomer is identical in form but negative.<sup>62</sup>

Potentially ORD and CD curves provide the same information about the absolute configuration of the enantiomer but the finite extension of the former outside of the absorption band envelope means that for systems having several optically active transitions of similar energy the ORD spectrum is often considerably more complicated than the CD. Transitions which are magnetic-dipole allowed will make the greatest contribution to the observed rotatory power, the magnitude of the contribution depending on the transition rotatory strength<sup>63,64</sup>

$$R_{ba} = \text{Im}\{(\alpha|\psi_e|b) \cdot (b|\psi_m|\alpha)\} = \rho\mu\cos\phi$$

where  $\text{Im}\{ \}$  denotes *imaginary part of*,

$\psi_m$  is the magnetic-dipole operator,

$\mu$  is the magnetic-dipole moment

and  $\phi$  is the angle between the directions of  $\rho$  and  $\mu$ .

Thus, transitions which are electric-dipole allowed but magnetic-dipole forbidden will make only a small contribution to the optical rotatory power.  $R_{ba}$  is maximal for transitions having parallel electric- and magnetic-dipole vectors, i.e.  $\phi = 0^\circ$ . Moffitt<sup>25,65</sup> indicated that only the "electronically allowed" (as opposed to "vibronic" - see Chapter 6) part of the electric-dipole oscillator strength,  $\psi_e$ , contributes to the rotatory strength.

The rotational strength of a transition may be determined<sup>12</sup> from the area under a CD peak as

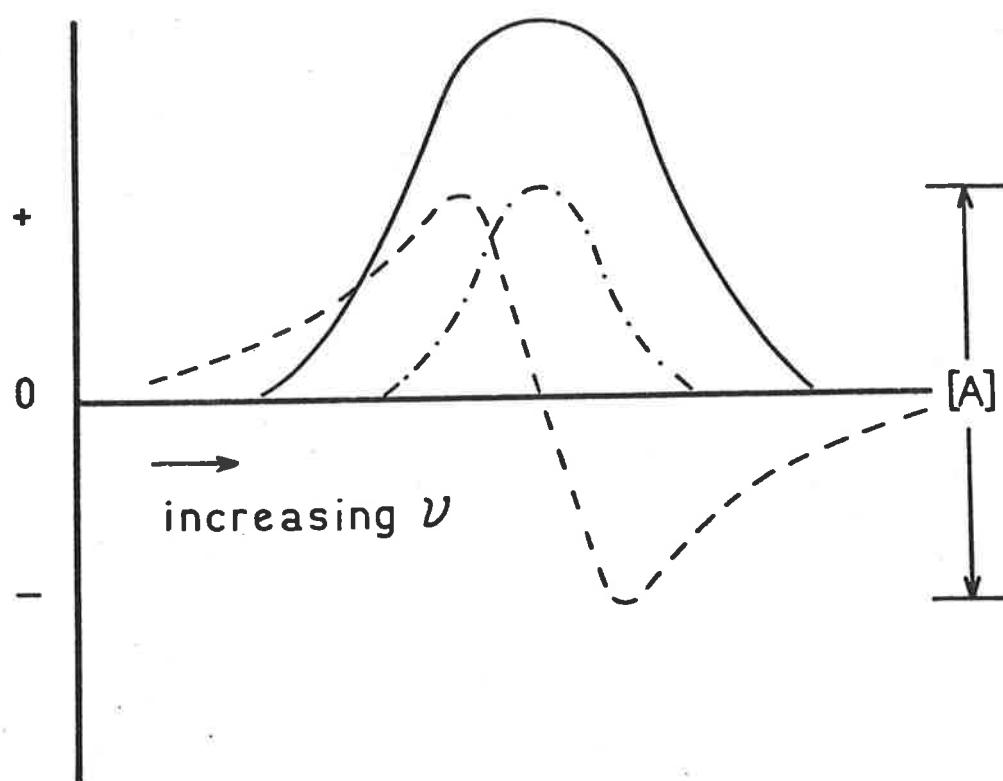

FIGURE A.1: POSITIVE COTTON EFFECT FOR AN ISOLATED TRANSITION.

— Absorption,  $\epsilon$ .

---- Molecular rotation,  $[M]$ .

-.-. Optical circular dichroism ( $\epsilon_L - \epsilon_R$ ) or ellipticity,  $\psi$ .

$$R_{ba} = \frac{3hc}{8\pi^3 N_1} \int_0^{\infty} \frac{(\text{ellipticity})}{\nu} d\nu \quad \text{c.g.s. units}$$

where *ellipticity* (in degrees) is a measure of the circular dichroism such that the molecular ellipticity

$$[\theta]_{\lambda}^t = 3300 (\epsilon_L - \epsilon_r) \text{ (degrees) cm}^{-1} \text{ mole}^{-1} \text{ litre.}$$

The measured ellipticity,  $\psi$ , is related to the molecular ellipticity in the same way that the measured optical rotation,  $\alpha$ , relates to the molecular rotation  $[M]_{\lambda}^t$ , i.e.

$$\text{Specific ellipticity } [\psi]_{\lambda}^t = \psi / ldp$$

where  $l$  = path length in decimetres,

$d$  = density of the solution,

$p$  = grams of solute per 100 grams of solution,

$t$  = temperature,

$\lambda$  = wavelength

and  $[\theta]_{\lambda}^t = [\psi]_{\lambda}^t M_w / 100$  is the molecular ellipticity in degrees

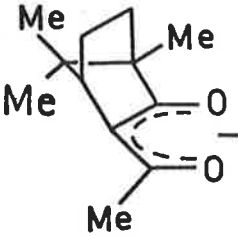

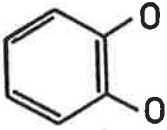

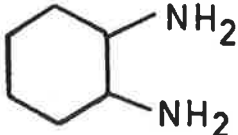

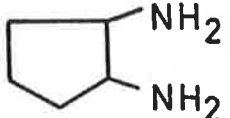

where  $M_w$  is the molecular weight.

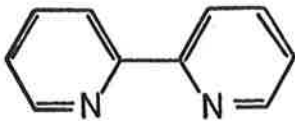

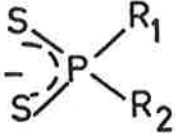

The amplitude  $[A]$ , (see Figure A.1), of the dispersion of molecular rotation,  $[M]$ , is related to the maximum circular dichroism of an isolated transition as

$$[A] = 4028 (\epsilon_L - \epsilon_r)_{\text{max}}$$

CHAPTER 1 THE STRUCTURE OF SODIUM (+)<sub>546</sub>-BIS(MALONATO)-  
ETHYLENEDIAMINECOBALTATE(III) DIHYDRATE.

1.1 STRUCTURE ABSTRACT

The structure of the sodium salt of (+)<sub>546</sub>-bis(malonato)ethylenediaminecobaltate(III),  $\text{Na (+)}_{546}[\text{Co}(\text{CH}_2(\text{CO}_2)_2)_2(\text{C}_2\text{H}_8\text{N}_2)].2\text{H}_2\text{O}$ , has been solved and refined by full-matrix least-squares to  $R_1 = 0.050$  using 838 integrated  $\text{MoK}\alpha$  photographic intensities. The lattice is orthorhombic, space group  $\text{P}_{2_1^2_1^2_1}$  (No. 19),  $a = 13.46$  (2),  $b = 14.24$  (2),  $c = 7.344$  (10) Å,  $V = 1408$  (5) Å<sup>3</sup>,  $Z = 4$ ,  $D_m = 1.78$  (2) g. cm<sup>-3</sup>,  $D_c = 1.80$ . The trigonal-bidentate complex ion exhibits approximate two-fold symmetry with the two malonate ligands adopting boat conformations and folding toward each other while the ethylenediamine ligand is dissymmetrically skewed oblique to the pseudo- $\text{C}_3$  axis of the anion. The absolute configuration of the complex ion is  $\Delta$ , in agreement with correlations from circular dichroism experiments.

1.2 EXPERIMENTAL

Racemic  $\text{Na}[\text{Co mal}_2 \text{ en}].x\text{H}_2\text{O}$  was prepared by the published method<sup>72</sup> but attempted resolution was unsuccessful due to low activity of the resolving agent. Recrystallization from aqueous solution of a sample of  $\text{Na (+)}_{546}[\text{Co mal}_2 \text{ en}].2\text{H}_2\text{O}$  supplied by Dr. A.M. Sargeson gave red-violet rectangular prisms, the majority of which exhibited

<sup>†1</sup> ten digit structure identifier.

{1,1,1;  $\bar{1},\bar{1},1$ } bevels at one end of the needle axis and were badly twinned; the faces parallel to the needle axis were of the form {1,1,0}. The space group and unit cell parameters were determined from zero and upper level precession and Weissenberg films recorded with  $MoK\alpha/Zrnf$  radiation ( $\lambda = 0.7107 \text{ \AA}$ ). The errors in the unit cell dimensions were estimated from multiple determinations of the constants for several crystals. Systematic absences of the form  $\{h00\}$ ,  $h = 2n + 1$ , occurred.

*Crystal Data* - as in structure abstract.

$$\mu_{MoK\alpha} = 13.3 \text{ cm}^{-1}.$$

$D_m$  by flotation in carbon tetrachloride/1,3-diaminopropane at 22°C.

Integrated photographic intensities were recorded for reciprocal layers  $h0l-h2l$  and  $Ok1-2kl$  using a Supper Buerger precession camera, three films per layer, exposure times 96, 36, 12 hours,  $MoK\alpha/Zrnf$ . Layers  $hk0-hk7$  were photographically recorded on triple film packs using a Nonius Weissenberg equi-inclination camera, exposure time increasing from 47 hours for  $hk0$  to 94 hours for  $hk7$ . 0.0013 (1) inch thick brass shims were placed between films one and two and two and three of the multifilm pack to increase the recording range with  $Mo$  radiation and a dummy film was placed in front of the first intensity recording film in an attempt to reduce the background film intensity due to the long wavelength scatter.

The crystal used for the intensity data collection was a rectangular prism 0.10 x 0.10 x 0.40 mm. mounted along the needle axis,  $c$ . This crystal was also used to generate a non-integrated  $hkl$  layer, using  $CuK\alpha/Ni\beta$  radiation, for subsequent determination of the absolute configuration of the anion. A microscope examination of the crystal following this period of data collection revealed signs of surface powdering but the diffraction spots remained sharp suggesting the powdering was probably only due to dehydration of the surface layers.

The  $Cu$  data were estimated visually against a calibrated intensity strip and the integrated intensities were measured with a Nonius II Microdensitometer, excluding systematic absences from the list and including unreliable reflections (e.g. on the white radiation streak of another reflection, spot distortion) and very weak reflections with markers ( $E$  and  $U$  respectively in the structure factor tables) which facilitated their special handling in the data reduction steps (AUFAC, AULAC) and permitted their exclusion from the least-squares refinement cycles (FUORFLS) while continuing to calculate their structure factors.

### 1.3 STRUCTURE SOLUTION AND REFINEMENT

The data reduction procedure used in scaling the raw photographic intensities and deriving the standard deviation of the scaled intensity for each unique reflection is summarised in Appendix II. Absorption corrections were not applied. All data were initially fitted to an

AUFAC weighting scheme having  $a = 0.0023$ ,  $b = 0.0098$ ,  $c = 0$ ,  $d = 0$ .

Reflections showing poor agreement were checked on all films on which they occurred. Because there were no precession data with  $l = 6$  or  $7$ , Weissenberg layers  $hk6$  and  $hk7$  were excluded from the inter-layer scaling sequence and the initial stages of structure refinement; they were subsequently introduced with scale factors determined from the other Weissenberg layers in proportion to exposure times.

The initial data set (excluding  $hk6$  and  $hk7$  data) comprised 889 unique reflections of which 181 were unobserved ( $U$ ) and 24 unreliable ( $E$ ). A Patterson synthesis using this data set yielded starting coordinates for the Co atom and the positions of all non-hydrogen atoms, other than the water oxygens, were obtained from a Fourier map phased by Co. Two cycles of least-squares refinement (684 data included) of the sixty positional parameters for the above atoms lowered  $R_1$  from 0.350 to 0.155. Both water oxygen atoms (expected from density measurements) were located in Fourier and difference maps computed at this stage. The difference map also indicated some thermal anisotropy of the metal atoms. The water oxygens were included in the atoms list and after a further two cycles refining positional parameters and isotropic temperature factors of all atoms except Co and Na, which were refined anisotropically, the refinement converged with  $R_1 = 0.069$  and  $R_2 = 0.058$  for the 684 reflections.  $G$ , the error in an observation of unit weight, was 3.827. Examination of the low  $\sin\theta$  data at this point showed no systematic deviations attributable to extinction and an extinction parameter

was not refined in the subsequent treatment. The sources for the atomic scattering factors are indicated in Appendix IV.

Hydrogen atom positional coordinates (other than for the water molecules) were calculated using PLANEH such that C-H = 1.02 Å, N-H = 0.95 Å with tetrahedral angles at C and N. The twelve hydrogens were introduced to the atoms list with fixed isotropic thermal parameters; the scaled *hk6* and *hk7* Weissenberg data were added to the data set increasing the total number of unique reflections to 1060 of which 838 were included in subsequent refinement cycles.  $R_1$  and  $R_2$  became 0.066 and 0.063 respectively, dropping to 0.059 and 0.051 after one cycle of positional and isotropic temperature factor refinement; Co and Na were refined anisotropically and the hydrogens were kept fixed (number of variable parameters,  $n = 98$ ).  $G = 3.292$ .

Calculation of the structure factors for the 38 pairs of *CuK $\alpha$ /Ni $\lambda$*  Weissenberg data ( $h \pm k1$ ) ( $\Delta f''_{CoCu} = 3.90$ ) indicated that the absolute configuration of the (+)<sub>546</sub>-anion was  $\Delta$  and not  $\Lambda$  as had been chosen (37 pairs agreed with the choice of  $\Delta$  while only the weakest pair of reflections contradicted such an assignment). Moreover, analogous calculations on the *MoK $\alpha$ /Zr $\lambda$*  data with  $\Delta f''_{CoMo} = 1.10$  gave  $R_1 = 0.058$ ,  $R_2 = 0.050$  for the  $\Delta$  configuration as opposed to values of 0.063 and 0.056 for  $\Lambda$ .

Although the structure seemed chemically reasonable at this stage, the increasing trend of  $Av \cdot \omega \Delta^2$  with increasing  $|F_o|$  indicated incorrect

weighting of the intensity data. Re-examination of the AUFAC inter-film scaling sequence of the *Mo* data (see parameters above and Appendix II) showed that the more intense data had been assigned standard deviations of the same order as the weaker reflections, i.e. the intense data carried weights which were relatively too large in the least-squares refinement cycles. The large standard deviations of the isotropic thermal parameters of the light atoms were also symptomatic of the inadequacy of this weighting scheme. To overcome this situation the data were fitted to a Cruickshank weighting scheme<sup>44a,46</sup> of the form

$$\sigma_{F_o} = (a + F_o + bF_o^2)^{1/2}$$

where  $a = 1.35$ ,  $b = 0.016$  and  $F_o$  is the square root of the observed unscaled intensity;  $w = 1/\sigma_{F_o}^2$ . A least-squares cycle using this weighting scheme and calculated for the  $\Delta$  absolute configuration with Co anomalous scattering terms included gave  $R_1 = 0.050$ ,  $R_2 = 0.066$  and  $G = 0.236$ ; the distribution of  $Av. w\Delta^2$  versus  $F_o$  flattened and the weighted  $R_2$  factor in all  $(\sin\theta)/\lambda$  ranges containing more than 30 reflections averaged 0.072 ( $\pm 0.015$ ). Estimated standard deviations of all refined parameters (positional and thermal) showed improvements ranging 30-50%.

The positions of the hydrogen atoms were recalculated and included in a final least-squares cycle refining positional and isotropic thermal parameters of all light atoms other than hydrogen; Co and Na were refined anisotropically. There was no change in the agreement

factors and the positional coordinates and estimated standard deviations which resulted were used in calculating the distance and angle parameters and their estimated standard deviations (given in parentheses) tabulated in the following section. Full-matrix anisotropic refinement of all non-hydrogen atoms ( $n = 201$ ) was not attempted for this structure because of prohibitive computing time requirements. A block refinement analogous to that used for anisotropic refinement of CADCOTHIOX (Chapter 3) could have been used.

Observed and calculated structure factors from the final least-squares cycle are listed in Table 1.1A and the  $CuK\alpha$  Friedel (or Bijvoet) pairs are given in Table 1.1B: for both tables  $F_o$ ,  $F_e \times 10$ ; the meaning of U and E is given in the text.

#### 1.4 STRUCTURE FIGURES AND TABLES

The figures and tables of structural parameters are collected together in this section preliminary to the discussion of section 1.5. The captions and table headings are, for the most part, self-explanatory; a few brief notes relevant to all three structures have been relegated to Appendix IV. Unit cell diagrams were not drawn for any of the structures presented in this work.

## 1.5 DESCRIPTION OF STRUCTURE AND DISCUSSION

The (+)<sub>546</sub>[Co mal<sub>2</sub> en]<sup>-</sup> anion has the  $\Delta$  absolute configuration (see discussion in Chapter 5). In the NADCOMALEN structure the complex ion exhibits approximate non-crystallographic two-fold symmetry with the six-membered malonate ligands adopting flattened boat conformations and folding toward each other. The ethylenediamine C-C bond is oblique to the pseudo-C<sub>3</sub> axis of the complex ion. There is extensive hydrogen bonding involving the two water molecules per asymmetric unit and the diamine nitrogens; Na<sup>+</sup> makes six close contacts with the malonate carboxyl and carbonyl oxygens but none with the water molecules. The conformational features of the  $\Delta$  complex ion and the atom labelling are shown in Figures 1.1 and 1.2; Figure 1.3 is an *ab* projection of the immediate environment of the anion with a small angular tilt around the horizontal (*a*) axis to better show the oxygen environment of Na<sup>+</sup>. The water molecules form a right-handed hydrogen bonded spiral of density around the 2<sub>1</sub> screw axes parallel to *c*; the hydrogen atoms of the water molecules were not located in the final difference map.

The various types of intermolecular and interior close contacts are listed in Tables 1.7, 1.8 and 1.9; not all are significant; the Na<sup>+</sup> ionic radius is 0.97 Å,<sup>80</sup> van der Waals radius of oxygen, 1.40 Å,<sup>81</sup> and acceptable hydrogen bond ranges are given<sup>74</sup> as N...O, 2.73-3.22 Å, and O...O, 2.49-3.15 Å. When comparing close contacts in the solid state with appropriate van der Waals radii sums it should be remembered that weak attractive forces between "non-nearest" neighbour atoms tend

45.

to contract the lattice; <sup>82,83</sup> limiting contacts 0.3-0.4 Å less than the van der Waals radii sum are not uncommon.<sup>84</sup> All close contacts in Table 1.9 are satisfactory.

Tables 1.3-1.6 detail the geometry of the anion. Failure to refine the non-metal atoms anisotropically has resulted in large estimated standard deviations (esd's) in their positional coordinates and the derived bond lengths and angles. The chemically equivalent Co-O, Co-N, N-C and C-C (malonate) bond lengths agree to better than one esd of an individual bond length. The mean Co-O bond length of 1.897 (8) Å is within  $3\sigma$  (see Appendix IV, note 3) of that reported for Co(acac)<sub>3</sub>, namely 1.898 (6) Å<sup>85</sup> and 1.872 (8) Å.<sup>86</sup> The less accurately determined<sup>87</sup> Co(ox)<sub>3</sub><sup>3-</sup> has two independent Co-O bonds of length 1.90 (3) Å and 1.95 (3) Å. The mean Co-N length (1.925 (17) Å) is close to that found<sup>88</sup> in [Co(NH<sub>3</sub>)<sub>6</sub>]I<sub>3</sub> but more than  $2\sigma$  shorter than the average Co<sup>III</sup>-N bond length in any of the tris (five-membered diamine ring) complexes listed in Table 8.1. The analogous bond lengths reported<sup>89</sup> for this anion in the (-)<sub>589</sub>[Co en<sub>2</sub>(NO<sub>2</sub>)<sub>2</sub>](+)<sub>589</sub>[Co mal<sub>2</sub> en] structure<sup>90</sup> were Co-O 1.90 (2) Å, Co-N 1.94 (2) Å; that structure refinement was based on visually estimated data and was limited to isotropic refinement of all thermal parameters. The esd's from the present refinement (NADCOMALEN) and Matsumoto and Kuroya's structure<sup>89</sup> are similar and the limiting factor would seem to be failure to perform full-anisotropic least-squares cycles rather than the quality of the visually estimated data as opposed to the microdensitometer intensities.<sup>91</sup>

The C-C bonds in all three ligands show the expected<sup>74</sup> shortening from the 1.54 Å paraffinic value; the mean C-N bond length, 1.474 (29) Å, is that listed<sup>74,92</sup> for a paraffin four-covalent nitrogen bond length. The mean carboxyl, 1.282 (17) Å, and carbonyl, 1.240 (18) Å, bond lengths agree to within 3σ of the two mean values; all four exocyclic oxygen atoms are involved in close contacts with Na<sup>+</sup> and/or possible hydrogen bonds (Tables 1.7 and 1.8, Figure 1.3). As only three structures of complexes containing chelated malonate ions have been reported<sup>89,93</sup> protracted discussion of the bond and torsion angles is not informative especially in view of their large esd's; in general the chemically equivalent bond angles agree within one standard deviation. The average C-C-C angle (117°) is closer to an ideal  $sp^2$  value (120°) than  $sp^3$  (109.5°) but is not as strained as that quoted in ref. 89, namely 125°.

Apart from the determination of the absolute configuration of the anion, the conformations of the two six-membered malonate rings are of special interest. There are several ways of describing the observed conformations, of which the torsion angle description (Table 1.6) is the most rigorous but at the same time the least conceptually satisfying. A more descriptive analysis is possible in terms of the two carboxyl oxygens and carbons of each malonate ligand, i.e. O<sub>1L</sub>, O<sub>2L</sub>, C<sub>11</sub>, C<sub>13</sub> and O<sub>3L</sub>, O<sub>4L</sub>, C<sub>31</sub>, C<sub>33</sub>; these four atom groups are closely planar whereas the Co and methylene carbon atom are significantly displaced to the same side of each plane (Table 1.4), giving two boat conformations. An equally satisfying description of these boat

conformers is that given in Table 1.5 where the displacement of the Co and methylene carbon from the respective ligand plane is expressed as an interplanar dihedral angle, it being understood that the Co and carbon atoms ( $C_{12}$ ,  $C_{32}$ ) lie on the same side of the relevant four atom plane.

Dreiding models give no clear indication of a preferred conformation for a chelated malonate ring, especially when the steric role of the carboxyl oxygen lone pairs is uncertain. This doubt concerning the lone-pairs precluded an energy minimization analysis analogous to those performed<sup>94,95</sup> for the five- and six-membered diamine ring systems. NMR studies<sup>31,32</sup> of  $[\text{Co mal}_2 \text{en}]^-$  and  $[\text{Co mal en}_2]^+$  were equally ambiguous. In view of the interionic contacts and hydrogen bonding in the NADCOMALEN structure it seemed probable that the conformation observed reflected crystal packing forces as much as any minimum energy conformation of the isolated ion. This hypothesis was supported by our subsequent determination of the CRMALTCOPN structure (Chapter 2) in which the malonate rings are significantly distorted from the boat conformation and also by the recent publication<sup>89,90</sup> of the structure of triclinic  $(-)_589[\text{Co en}_2(\text{NO}_2)_2](+)_589[\text{Co mal}_2 \text{en}]$ .

The anion in this latter structure also exhibits approximate non-crystallographic two-fold symmetry with the en ligand again adopting an oblique conformation relative to the pseudo- $C_3$  axis; the malonate rings, however, are more flattened than those found in the present study. In neither structure analysis were weighted least-squares planes calculated and the esd's in the deviations of the atoms from the mean

planes are not available. Matsumoto and Kuroya have described<sup>89</sup> the malonate rings in their structure as "approximately planar"; given that the deviations from planarity are small (and probably lack significance) both malonate rings in the  $[\text{Co en}_2(\text{NO}_2)_2][\text{Co mal}_2 \text{ en}]$  structure are more accurately described as distorted skew conformations. It is not possible to decide the orientation of the ring backbones relative to the pseudo  $C_3$ -axis (i.e. whether *tel* or *ob*<sup>96</sup>) from the distortions as listed; calculations from the positional coordinates are required. Intermolecular hydrogen bonding is again seen<sup>89</sup> to be important in determining the precise conformation of the Co-malonate chelate rings. Further discussion of malonate ring conformation is made in Chapter 2.

A final point of interest is the oblique conformation<sup>1</sup> observed for the ethylenediamine ligand in the  $[\text{Co mal}_2 \text{ en}]^-$  ion in both structures; this particular ring conformation has now been observed in structures of several transition metal complexes and the precise geometry seems to depend on the hydrogen bonding<sup>92,97</sup> and van der Waals interactions. In NADCOMALEN the carbon atoms of the en ligand are dissymmetrically placed either side of the  $\text{CoN}_1\text{N}_2$  plane; similar ring asymmetry has been found in the structure of  $[\text{Cu en}_2](\text{SCN})_2$ .<sup>98</sup>

CHAPTER 2 THE STRUCTURE OF  $(-)_589$ -TRIS( $(-)_589$ 1,2-DIAMINOPROPANE)-  
COBALT(III)  $(+)_589$ -TRIS(MALONATO)CHROMATE(III) TRIHYDRATE.  
 $(-)_589[\text{Co}(-)\text{pn}_3](+)_589[\text{Cr mal}_3] \cdot 3\text{H}_2\text{O}$ , CRMALTCOPN.

2.1 STRUCTURE ABSTRACT

The absolute configuration of the  $(+)_589$ -tris(malonato)chromate anion,  $(+)_589[\text{Cr}(\text{CH}_2(\text{CO}_2)_2)_3]^{3-}$ , has been determined as  $\Lambda$  by a single crystal structure analysis of the salt formed with  $\Delta(-)_589$ -tris( $(-)$ propylenediamine)cobalt,  $(-)_589[\text{Co}(-)(\text{C}_3\text{H}_{10}\text{N}_2)_3]^{3+}$  as cation. The structure  $(-)[\text{Co}(-)\text{pn}_3](+)[\text{Cr mal}_3] \cdot 3\text{H}_2\text{O}$  has been refined by full-matrix least-squares to a conventional  $R$  factor of 0.073 using 435 integrated photographic data. The lattice is rhombohedral, space group  $R_{32}$  (No. 155), hexagonal parameters  $a = 16.12$  (2),  $c = 10.07$  (2) Å,  $U = 2265$  (7) Å<sup>3</sup>,  $Z = 3$ ,  $D_c = 1.53$ ,  $D_m = 1.52$  (2) g. cm<sup>-3</sup>. Both complex ions are disordered on 32-symmetry sites in the hexagonal unit cell and are linked to each other and to the water molecules by hydrogen bonds. The cation adopts the expected  $\Delta(\lambda\lambda\lambda)$  conformation with the exocyclic methyl groups equatorial; the metal-malonate ring skeleton in the anion is planar except for the methylene carbon. The absolute configuration of the anion is opposite an earlier assignment based on circular dichroism data.

2.2 EXPERIMENTAL

Partial resolution of  $\text{K}_3[\text{Cr mal}_3]$  as the strychnine salt has been reported previously.<sup>99</sup> Attempted resolution of the complex by this

method was unsuccessful: crystallization of the racemic potassium salt proved difficult because of its extreme solubility and apparent sensitivity to slight changes in pH. The dichroic blue-green micro-crystalline powder obtained by reduction of potassium dichromate<sup>99,100</sup> was similar (IR-visible spectrum, analysis, X-ray powder photos) to the product derived from a preparation after the method of Lapraik<sup>101,102</sup> starting with freshly prepared  $\text{Cr}(\text{OH})_3$ .

*Analysis*  $\text{K}_3[\text{Cr}(\text{C}_3\text{H}_2\text{O}_4)_3] \cdot 3\text{H}_2\text{O}$

*calc.* Cr, 9.82: K, 22.16: C, 20.41: H, 2.28.

*found* 9.40: 22.49: 20.81: 2.06.

(C,H, by microanalysis: permanganate determination<sup>103-105</sup> of malonate was not reproducible. Cr, spectrophotometrically as chromate at 370 nm on oxidation with hydrogen peroxide over three days.<sup>102</sup> K, gravimetric analysis as  $\text{K}_2\text{Na}[\text{Co}(\text{NO}_2)_6] \cdot \text{H}_2\text{O}$  dried at  $110^\circ\text{C}$  to constant weight.<sup>104</sup>)

Elution of independently prepared  $\text{K}_3$ - and  $\text{Na}_3[\text{Cr mal}_3]$  samples from AG1-X4 anion exchange resin in the chloride form showed three to five bands for all preparations. No attempt was made to determine the nature of the species in the minor bands (probably bis- and mono-malonates<sup>106</sup>) since the major component always eluted last with aqueous chloride solution suggesting a predominance of the trivalent tris-chelate. An infra-red spectrum of a potassium bromide disc of one preparation was almost identical with the published spectrum<sup>107</sup> and as all preparations were subsequently shown to give identical crystalline precipitates with  $(-)[\text{Co}(-)\text{pn}_3]^{3+}$  further characterization was not considered necessary.

Attempted resolution of  $[\text{Cr mal}_3]^{3-}$  with  $(+)\text{[Co en}_3]^{3+}$ ,  $(+)\text{[Ni phen}_3]^{2+}$  and strychnine gave no precipitation from moderately concentrated solutions.  $(-)\text{[Co(-)pn}_3]^{3+}$ , however, initiated instantaneous growth of fine needles from dilute solutions;<sup>†1</sup> these crystals had appreciable solubility only at pH levels well removed from neutrality and since such conditions could be expected to induce racemization, if not complete rupture of one or both complex ions, larger crystals clearly could not be prepared by recrystallization. Crystals suitable for intensity data collection were prepared by layering a solution of *trans*- $(-)\text{[Co(-)pn}_3]\text{Br}_3$  on a more dense solution of  $\text{K}_3[\text{Cr mal}_3]\cdot 3\text{H}_2\text{O}$ , well-formed crystals growing over several hours. *trans*- $\text{Co}(\text{pn})_3^{3+}$  precipitated crystals of larger cross-section than did the *cis*-cation but subsequent determination of the space group and lattice constants of both types of crystal showed them to be identical. The bronze prisms were equilateral-triangular in section and showed extinction parallel to the needle axis; the triangular section was isotropic, the crystal morphology suggesting a trigonal system. Precipitation studies (see Chapter 5) showed that  $(-)\text{[Co(-)pn}_3]^{3+}$  co-crystallizes with the  $(+)\text{[Cr mal}_3]^{3-}$  enantiomer.

<sup>†1</sup> P.F. Crossing<sup>95</sup> had been attempting to verify a claimed<sup>108</sup> separation of the *cis*- and *trans*- geometric isomers of  $(-)\text{[Co(-)pn}_3]^{3+}$ : samples supplied by Dr. T.E. MacDermott. All anions tested had given precipitates of the two samples which were indistinguishable<sup>109,110</sup> by X-ray powder diffraction. It was decided to try  $[\text{Cr mal}_3]^{3-}$  and the ensuing crystallization was so rapid that it was difficult to prepare sufficiently large crystals for space group determinations.

Preliminary Weissenberg and precession photographs of several crystals confirmed the trigonal system: indexing on hexagonal axes established the condition limiting observed reflections as  $-h + k + l = 3n$ . Coupled with the requirement for optical activity this condition restricts the possible space groups to  $R_3$  and  $R_{32}$ .  $CuK\alpha/Ni\beta$  photographs confirmed 32-point symmetry and hence space group  $R_{32}$ ; with  $Z = 3$  the Co and Cr atoms lie on 32-symmetry sites and the cation must be disordered since its maximum symmetry is  $C_1$  for *trans* and  $C_3$  for *cis*. Subsequent structure refinement showed that the anion is similarly disordered although 32-symmetric skew conformations of  $[Cr\ mal_3]^{3-}$  are possible.

*found* 30.26: 11.52: 5.71.

(Qualitative microanalysis on crushed crystals of the diastereoisomer was negative for  $K^+$  and  $Br^-$ .)

The *trans* (-)  $[Co(-)pn_3]^{+}[Cr\ mal_3]^{3-} \cdot 3H_2O$  crystal used to generate

the intensity data set was a needle 0.40 mm. long and triangular in section; triangle edges 0.15 mm.. It was mounted along the needle axis. Preliminary oscillation photographs showed the intensity of the  $l = 2n + 1$  layers to be much less than that of the even layers, a destructive interference effect consequent on the Co and Cr atoms being separated by  $c/2$  in the real unit cell. Using *MoK $\alpha$ /Zr $\beta$*  radiation integrated triple film packs of Weissenberg equi-inclination layers *hk0-hk8*, *hk10* were recorded, exposure times ranging 1-5 days for  $l = 2n$  and 4-8 days for the  $l = 2n + 1$  layers. The structure of the film pack was identical to that described in Chapter 1. Reciprocal layers *h0l-h3l* were recorded as integrated precession photographs for the same crystal without remounting. Triple exposures ranging 12-72 hours were recorded for the four levels. The integrated data were measured photometrically with a Nonius II microdensitometer.

### 2.3 STRUCTURE SOLUTION AND REFINEMENT

The scaling of the photographic intensity data is described in Appendix II. Lack of meshing precession data necessitated introduction of the *hk7* Weissenberg reflections at a subsequent stage and initial structure solution was made excluding this set of 25 unique reflections (initial data set: 426 unique reflections of which 35 were unobserved). Anomalies in the distribution of  $\Delta v \cdot \omega \Delta^2$  vs.  $|F_o|$  in the final stages of refinement again indicated a relative overweighting of the most intense data in the original AUFAC inter-film scaling procedure, resulting in

chemically unreasonable bond lengths and angles. The initial weighting scheme was modified in the final stages of refinement when the  $hk\ell$  Weissenberg data were introduced to the reflection list.

For  $(-)[\text{Co}(-)\text{pn}_3](+)[\text{Cr mal}_3]\cdot 3\text{H}_2\text{O}$  in space group  $R_{32}$  ( $Z = 3$ ) the metal atoms occupy the 32-symmetry positions at  $(0,0,0)$  and  $(0,0,\frac{1}{2})$ . An initial Fourier map phased on Co and Cr atoms at these two sites showed the expected  $\bar{3}m$  Laue symmetry. This map, using only the  $\ell = 2n$  data, had an additional inversion centre at  $(0,0,\frac{1}{4})$  due to an effective halving of the  $c$  lattice repeat. The  $\ell = 2n + 1$  data were excluded from the initial Fourier maps because of the relatively small contribution of the metal atoms to these odd order reflections. This was, however, an unfortunate approach since the Co and Cr sites then become identical and only one unique donor atom position ( $2 \overset{\circ}{\text{Å}}$  from the metal and lying on a mirror plane of  $\bar{3}m$ ) was found; the implication of this in terms of the relative orientation of the  $\text{CoN}_6$  and  $\text{CrO}_6$ -cores was initially unclear. Smaller peaks at distances further removed from the metal atoms were also observed.

This large donor atom peak (at 0.062, 0.124, 0.100) corresponded to an orientation of the  $\text{ML}_6$ -cores which maintained the  $C_3$  and pseudo- $C_2$  axes of the complex ions parallel to the crystallographic axes but although a Fourier map based on this model ( $\text{CrO}_6$ ,  $\text{CoN}_6$  only) gave several possible new atom sites, the malonate and propylenediamine ligands remained convoluted about both metal positions, making interpretation difficult ( $R_1 = 0.292$ ). Introduction of the  $(-)[\text{Co}(-)\text{pn}_3]^{3+}$  complex with the correct  $\Delta(\lambda\lambda\lambda)$  configuration at one

site gave  $R_1 = 0.234$  ( $R_1 = 2n = 0.147$ ,  $R_1 = 2n + 1 = 0.508$ ) but inclusion of possible water and malonate ligand atoms at this stage gave no significant improvement. Two cycles of least-squares refinement of the light atom positions and isotropic temperature factors of all atoms in this preliminary model lowered  $R_1$  to 0.209.

Inclusion of the even and odd data in a Fourier calculation based on this most recent model gave a 32-symmetric map lacking a false 32-position at  $0,0,1/4$ . This map revealed the position of the one unique water molecule and suggested a  $\Lambda$  configuration for  $(+)[Cr\ mal_3]^{3-}$  with the malonate ligand spanning the  $+x$  axis: for the  $\Delta(-)[Co(-)pn_3]^{3+}$  ion the pn ligand spanned the  $-x$  axis. The choice of the  $\Lambda$  or  $\Delta$  absolute configuration for the anion corresponds not merely to a choice of absolute configuration but to a choice between two different structures, namely  $\Delta Co \Delta Cr$  and  $\Delta Co \Lambda Cr$ . Even knowing the relative absolute configurations of the two complex ions, however, there remained the problem of fixing the malonate ligand conformation since the anion appeared to be disordered on the 32-symmetry site rather than adopting a 32-symmetric tris-skew conformation. The carboxyl carbon and oxygen atoms were approximately coplanar with Cr and corresponded to 32-symmetry but the methylene carbon atom lay just off the two-fold axis and the carbonyl oxygen peak was broad and of indeterminate weight. Introduction of all atoms to the model (including the carbonyl oxygen  $O_2C_1$  with unit multiplier) resulted in the following  $R$  factors after two cycles of least-squares refinement of the positional parameters of the light atoms and the isotropic temperature factors of the metals -

$R_1 = 0.145$  ( $R_{\mathcal{L} = 2n} = 0.125$ ,  $R_{\mathcal{L} = 2n + 1} = 0.209$ ) for 426 data of which 377 were included in the least-squares cycles, unit weights. Changing to the weighting scheme refined in the data scaling routine gave, after two further cycles of full-least-squares positional and isotropic refinement ( $n = 33$  variable parameters),  $R_1 = 0.092$  ( $\mathcal{L} = 2n$ , 0.087;  $2n + 1$ , 0.152). At this stage gross outliers in the data set were checked for incorrect measurement.

Fourier and difference maps computed for this model revealed appreciable anisotropy in the metal vibrations and also showed the carbonyl oxygen as included to be an average of two positions of approximately equal weight; this latter is as expected for a puckered non two-fold symmetric malonate ring. The  $\text{Co}^{2+}$  and  $\text{Cr}^{2+}$  scattering curves were modified to allow for anomalous dispersion (see Appendix IV, note 1) and all atoms refined anisotropically, except  $\text{OH}_2\text{OCo}$  which was restricted to a position on the two-fold axis through the Co atom and refined isotropically with its multiplier fixed at  $\frac{1}{2}$ . The agreement factors at convergence were  $R_1 = 0.072$ ,  $R_2 = 0.063$ ,  $R_{\mathcal{L} = 2n} = 0.069$ ,  $R_{\mathcal{L} = 2n + 1} = 0.106$ ,  $G = 1.98$  for 426 data of which 377 were included in the least-squares refinement cycles.  $R_{\mathcal{L} = 2n + 1}$  is most sensitive to the refinement of the light atoms since the metal contribution to the odd data corresponds to a maximum of only three electrons. The methylene carbon atom ( $\text{C}_2$ ) and the split carbonyl oxygen ( $\text{O}_2\text{C}_1$ ,  $\text{O}_2\text{C}_1\text{A}$ ) were non-positive definite. The correlation matrix showed several large correlation factors (ca. 0.5-0.8) between positional parameters which

could be related by  $\bar{3}m$  operations (see also ref. 45). Derived bond lengths and angles showed some disturbing deviations from the expected values, e.g. the C-C bond of the pn ligand was 1.62 Å (see discussion and Table 2.9).

Inclusion of the 25  $hk\ell$  data at this point increased  $R_2$  to 0.112 and worsened the distribution of  $\Delta v$ .  $w\Delta^2$  vs.  $|F_o|$ . As with the NADCOMALEN structure (Chapter 1) the fault seemed to lie in the initial weighting schemes chosen in the data scaling routine, but rather than apply a modified weighting scheme in the least-squares cycles it was decided to adopt a more realistic curve in the inter-film scaling sequence, at the same time introducing the  $hk\ell$  data. The unscaled Weissenberg and precession data were weighted independently applying average schemes derived from the earlier data reduction sequence. The parameters for the new schemes were (with those used initially in parentheses) - Weissenberg;  $a = 0.0484$  (0.0113),  $b = -0.0037$  (0.0066),  $c = 0.3024$  (0.0928),  $d = 0.0109$  (0.0078) - Precession;  $a = 0.0420$  (0.0749),  $b = -0.0017$  (-0.0040),  $c = 0$  (0.0073),  $d = 0$  (0.0086). These weighting scheme changes resulted in a relative "down-weighting" of the more intense Weissenberg data: the final data set comprised 451 unique reflections of which 38 were unobserved (*U*) and 16 unreliable (*E*).

The hydrogen atoms bonded to the N and C atoms of the pn ligand were included at calculated positions (program PLANEH) with fixed positional and isotropic thermal parameters; no attempt was made to introduce the methyl group hydrogens or the disordered hydrogen atoms attached to the

methylene carbon of the malonate ligand. The 38 unobserved reflections were included in the least-squares data set and after three cycles of anisotropic refinement ( $\text{OH}_2\text{OCo}$  isotropic) employing the modified weighting scheme all variable parameter shifts were less than 1/3 of the relevant esd (except for the anisotropic thermal parameters of  $\text{O}_2\text{C}_1\text{A}$  which remained non-positive definite). The agreement factors at convergence were  $-R_1 = 0.073$ ,  $R_2 = 0.083$ ,  $R_{\Sigma} = 2n = 0.064$ ,  $R_{\Sigma} = 2n + 1 = 0.121$ ,  $G = 2.01$  for 451 data of which 435 were included in the least-squares cycles, 80 variable parameters; the distribution of  $\Delta v$ .  $w\Delta^2$  vs.  $|F_o|$  was flat. The bond lengths and angles were more chemically reasonable and apart from atom  $\text{O}_2\text{C}_1\text{A}$  the thermal parameters seemed realistic (the problem with  $\text{O}_2\text{C}_1\text{A}$  is thought to arise because of its high correlation with  $\text{O}_2\text{C}_1$  to which it is related by an approximate non-crystallographic mirror plane coincident with the Cr,  $\text{O}_1$ ,  $\text{C}_1\text{O}_1$ , atoms<sup>45</sup>). High coefficients in the correlation matrix are considered to reflect non-orthogonality of the crystal  $a$  and  $b$  axes.<sup>45,111</sup>

A final difference Fourier revealed peaks of ca.  $\frac{1}{2}$ -electron in height on the  $z$  axis adjacent to the metal atom sites and also showed some anisotropy of  $\text{OH}_2\text{OCo}$  parallel to  $z$ . The light atoms all occupied saddle points between peaks  $0.05 e^-$  in height.

Observed and calculated structure factor amplitudes from the final least-squares cycle are listed in Table 2.1 with  $F_o$ ,  $F_c$  both  $\times 10$ .

TABLE 2.1 FINAL  $|F_o|$  AND  $|F_c|$  FOR  $(-)[Co(-)pn_3](+)[Cr\ mal_3] \cdot 3H_2O$ :  $\Delta\Delta$  CONFIGURATION.

#### 2.4 STRUCTURE FIGURES AND TABLES

The figures and tables of structural parameters for the CRMALTCOPN structure are collected together here preliminary to the discussion of section 2.5. The structural parameters as given in the following tables correspond to the atom labelling and orientation of figures 2.1 and 2.2, where a ' superscript denotes a two-fold related atom.

#### 2.5 DESCRIPTION OF STRUCTURE AND DISCUSSION

(+)[Cr mal<sub>3</sub>]<sup>3-</sup> has a  $\Lambda$  absolute configuration by comparison with the known  $\Delta(\lambda\lambda\lambda)$  configuration of (-)[Co(-)pn<sub>3</sub>]<sup>3+</sup>; this assignment is contrary to an earlier assignment<sup>27,28</sup> based on the aqueous solution CD spectrum. Both complex ions are C<sub>3</sub> symmetric but are disordered<sup>†2</sup> on 32-symmetry sites of the R<sub>32</sub> space group with the water molecules occupying two-fold sites between the pn ligands of the cation, directly under (and above) each malonate ring.

The Co and Cr atoms are 5 Å<sup>o</sup> apart along *c* with the pn and mal ligands spanning the -*a* and +*a* crystallographic directions respectively. The carboxyl oxygen (O<sub>1</sub>) of the malonate ligand is strongly hydrogen bonded to N<sub>1</sub> through N<sub>1</sub>H<sub>2</sub> while the water oxygen makes close contacts with N<sub>1</sub> through N<sub>1</sub>H<sub>1</sub> and with the carbonyl oxygens of anions on adjacent three-fold axes (Table 2.7, Figures 2.2 and 2.3). If a freely rotating methyl group is taken<sup>80</sup> as having an effective non-bonded radius of

---

†2 This disorder renders the *cis*- and *trans*-cations indistinguishable and single crystal *CuK $\alpha$ /Ni $\lambda$*  equi-inclination and precession photographs of several (-)[Co(-)pn<sub>3</sub>](+)[Cr mal<sub>3</sub>].3H<sub>2</sub>O crystals grown from the supposedly *cis*- and *trans*-(-)[Co(-)pn<sub>3</sub>]Br<sub>3</sub> samples confirmed the R<sub>32</sub> space group in all cases (this preliminary study in conjunction with P.F. Crossing).

61.

- a. the angle ω is defined by figure 7.1. The values at completion of refinement with the new weighting scheme were 48.0° and 60.2° for the cation and anion respectively (Chapter 8).

$2.0 \text{ \AA}$  the two close contacts less than  $3.1 \text{ \AA}$  (Table 2.8) are noteworthy; however, they are avoidable by a more specific ordering of the ions on adjacent symmetry sites.

Some relevant literature bond lengths are quoted in Chapter 1 and are comparable with those observed here, particularly for the cation which has the predicted tris(1e1) conformation with the C-C bond of the pn ring being held parallel to the  $C_3$  axis by the requirement that the methyl substituent occupy the energetically most favourable equatorial position.<sup>1</sup> The extent of this parallelism is emphasized by the interligand Co,  $C_1, C_1'$  interplanar dihedral angle,  $119.7 (1.3)^\circ$ . The interplanar dihedral angle between the Co,  $N_1, N_1'$  planes,  $97.1 (1.0)^\circ$ , indicates significant distortion of the  $\text{CoN}_6$  first coordination sphere from an idealized geometry having interplanar angles of  $90^\circ$  (this distortion is discussed further in Chapter 8).  $C_1H_1$  in the atoms list (Table 2.2) corresponds to the position of the two-fold disordered methyl group,  $C_1ME$ ; both were input with multipliers of  $\frac{1}{2}$ .

A tris-malonate anion has  $D_3$  symmetry only if the methylene carbon ( $C_2$ ) lies on a two-fold axis through the metal ion, i.e. a completely flattened ring conformation or a symmetrical skew form; in CRMALTCOPN  $C_2$  is displaced  $0.71 \text{ \AA}$  from the mean five atom plane through Cr,  $O_1, O_1', C_1O_1, C_1O_1'$ . The methylene carbon atom is also displaced from the hypothetical mirror plane of an ideal chair, boat or flattened conformer (viz.  $C_1O_1-C_2$  is  $1.56 (4) \text{ \AA}$  whereas  $C_1O_1'-C_2$  is  $1.61 (4) \text{ \AA}$ ) with consequent changes in bond and torsion angles (Tables 2.3 and 2.6).

Therefore in the 32-disordered arrangement the methylene carbon and the carbonyl oxygen atoms are split. The non-symmetry equivalent  $O_2C_1$  and  $O_2C_1A$  sites are  $0.63 (5) \overset{\circ}{\text{Å}}$  apart.

The  $Cr-O_1$  bond length,  $1.953 (7) \overset{\circ}{\text{Å}}$ , compares well with that found in  $Cr(acac)_3$ ,<sup>112</sup>  $1.956 (7) \overset{\circ}{\text{Å}}$ ,  $Cr(gly)_3$ ,<sup>113</sup>  $1.964 (1) \overset{\circ}{\text{Å}}$ , and  $(+)Cr((+)atc)_3$ ,<sup>114,115</sup>  $1.968 (10) \overset{\circ}{\text{Å}}$ . The carboxyl carbon-oxygen bond length ( $O_1-C_1O_1$ ,  $1.262 (18) \overset{\circ}{\text{Å}}$ ) is the same as the average carbonyl bond length ( $C_1O_1-O_2C_1$ ,  $C_1O_1-O_2C_1A$ ). The mean anion C-C bond length,  $1.585 (25) \overset{\circ}{\text{Å}}$ , is significantly longer than that found in the NADCOMALEN structure ( $1.50 (2) \overset{\circ}{\text{Å}}$ ); associated with this bond lengthening is a contraction of the angle at the methylene carbon from a value approximating the ideal  $sp^2$  value to within one esd of the ideal tetrahedral angle, e.g. in CRMALTCOPN the C-C-C angle is  $108.1 (2.4)^\circ$ , in NADCOMALEN  $117.2 (1.8)^\circ$  and in  $(-)[Co en_2(NO_2)_2](+)[Co mal_2 en]$ <sup>89</sup> where the average C-C bond length in the malonate rings is  $1.48 \overset{\circ}{\text{Å}}$  this angle is  $125^\circ$ . The high standard deviations in the individual bond angles in all three structures preclude detailed discussion of the individual bond and torsion angles.

The relative skew of the  $O_1\dots O_1'$  and  $C_1O_1\dots C_1O_1'$  lines about the two-fold axis is barely significant at a  $3\sigma$  level ( $3.85 (98)^\circ$ ) although larger than that found in NADCOMALEN; the displacement of the carboxyl oxygens  $\pm 0.09 \overset{\circ}{\text{Å}}$  either side of the  $Cr, C_1O_1, C_1O_1'$  plane is about half that observed in Matsumoto and Kuroya's structure<sup>89</sup> (see Chapter 1). In CRMALTCOPN the skew is such that the  $Cr, C, C$  plane is more nearly

parallel to the three-fold axis of the anion than is the Cr,O,O plane, as shown by the interligand interplanar dihedral angles ( $96.86 (98)^\circ$  and  $91.65 (96)^\circ$  respectively). This twisting of the ligand backbone relative to the  $ML_6$ -core in  $[Cr mal_3]^{3-}$  is discussed in section 8.2.

Mean-square amplitudes of thermal vibration were not computed but the anisotropic thermal ellipsoids of the non-metal atoms are shown in the figures; the temperature factor of atom  $O_2C_1A$  was non-positive definite and the minimum thermal ellipsoid as drawn serves only to indicate the direction of maximum vibration. Unfortunately, because figures 2.1 and 2.2 are views parallel to  $c$ , the thermal ellipsoids as drawn are of limited value in deciding the directions of maximal vibration. The methylene carbons of the pn ligand vibrate appreciably perpendicular to the Co,C,C plane while the ellipsoid of  $C_1ME$  is elongated radially. In the anion the methylene carbon shows maximum vibration perpendicular to the C,C,C plane while the other malonate ring atoms exhibit appreciable vibration perpendicular to the mean  $Cr,O_1,O_1',C_1O_1,C_1O_1'$  plane.

The most alarming feature of the CRMALTCOPN structure refinement was the significant change in some of the bond lengths and angles of the converged model on modification of the weighting of the intensity data: see Table 2.9 for some bond length and angle parameters for the converged structure based on the initial weighting scheme. For the tris-malonate ion the relevant angular parameters (see Chapters 7 and 8) from the final converged model are not significantly different from those of a

$D_{3d}$  symmetric  $ML_6$ -core; it would be more satisfactory if we could feel certain that this represents reality and not just a fortuitous dependence on the particular weighting of the intensity data. The structure refinement should be repeated, preferably using an excess of "correctly" weighted diffractometer data; it is important that more  $l = 2n + 1$  data be used in the refinement since these are relatively most sensitive to the refinement of the light atoms. The time required to record such data photographically became increasingly prohibitive at high  $\mu$  angles.

*Malonate Ring Conformation -*

Two important conclusions emerge from the three known structures of chelated malonate ligands. Firstly, the exocyclic carbonyl oxygens are always likely to participate in strong intermolecular hydrogen bonds and ionic close contacts resulting in a greater variety of conformations than is to be expected for the analogous six-membered diamine ring complexes. Second, because of this strong inter-molecular interaction the carbonyl oxygen bond is unlikely to be found significantly shorter than the intra-ring carboxylic C-O bond, at least not when using photographic intensities.

Notwithstanding the probable importance of intermolecular forces in determining the malonate ring conformations some observations of an intramolecular nature are worthwhile.

The mean intra-ring inter-carboxyl oxygen distance in the malonate rings of NADCOMALEN (i.e.  $O_1L \dots O_2L$ ,  $O_3L \dots O_4L$ ) is  $2.77 \text{ \AA}$ ; the mean

inter-carboxyl carbon atom distance ( $C_{11}\dots C_{13}$ ,  $C_{31}\dots C_{33}$ ) is 2.56 Å. The corresponding distances in CRMALTCOPN are  $O_1\dots O_1' = 2.72$  Å,  $C_1O_1\dots C_1O_1' = 2.57$  Å. In the present structure the C,C,C plane makes an angle of  $50.1^\circ$  with the  $O_1, O_1', C_1O_1, C_1O_1'$  plane whereas in NADCOMALEN this angle averages  $28.9^\circ$ . The agreement of the intra-ring non-bonded vectors in these two structures suggests that the smaller average value of this intra-ring dihedral angle in the  $[\text{Co mal}_2 \text{ en}]^-$  ion may in part be due to potential unfavourable intramolecular close contacts between the two malonate ligands; the relevant interactions in the refined NADCOMALEN structure are  $C_{12}H_1\dots C_{33}$ , 3.34 Å,  $C_{12}H_1\dots O_4L$ , 2.75 Å,  $C_{32}H_2\dots O_2L$ , 2.70 Å,  $C_{32}H_2\dots C_{13}$ , 3.11 Å. Increasing the intra-ring dihedral angle beyond ca.  $30^\circ$  in the  $[\text{Co mal}_2 \text{ en}]^-$  ion would result in strong repulsion between the above atom pairs. Although the malonate methylene hydrogen atoms were not included in the CRMALTCOPN refinement it is not difficult to see that the planarity of the five atoms ( $\text{Cr}, O_1, O_1', C_1O_1, C_1O_1'$ ) permits a larger dihedral angle with the  $C_1O_1, C_2, C_1O_1'$  plane before there is appreciable interaction of a donor oxygen of one malonate ligand with a methylene hydrogen of the other ligand. The dihedral angle between the tri-atomic M,O,O and C,C,C planes is ca.  $52^\circ$  for the three independent malonate rings (CRMALTCOPN,  $50.1 (2.7)^\circ$ ; NADCOMALEN,  $52.8 (2.5)^\circ$ ,  $53.4 (3.0)^\circ$ ), a geometry quite different from that found<sup>89</sup> in the  $[\text{Co en}_2(\text{NO}_2)_2][\text{Co mal}_2 \text{ en}]$  structure.

If the malonate ligands in  $[\text{Co mal}_2 \text{ en}]^-$  folded toward the en ligand to the same degree that they fold toward each other in the NADCOMALEN

structure the interaction between the amine hydrogen atoms and the malonate methylene protons would be impossibly short; that a more flattened conformation of the malonate ring is acceptable has already been shown.<sup>89</sup> As mentioned previously, lack of suitable potential functions incorporating the steric effects of electron lone-pairs has precluded vapour-phase energy minimization calculations of the chelated malonate systems. Lone-pair/lone-pair repulsions have elsewhere been considered<sup>116-118</sup> stronger than atom/atom interactions<sup>81,119</sup> with lone-pair/bonded-pair repulsions being intermediate in strength. Only in the completely flattened ring conformation are all lone-pairs (on the donor oxygens) and bonding-pairs (M-L, C=O, C-H) maximally staggered; for a chair conformation they are maximally eclipsed and for boat and skew conformers some interactions are eclipsed and others are gauche. Correct representation of these interactions will be important in assessing the relative energies of the various malonate ring conformations but it is perhaps noteworthy that the low energy chair conformation commonly found<sup>94,120-126</sup> for chelated tn ligands (all ring atoms except the coordinated metal tetrahedral) is not approximated by any of the five crystallographically independent malonate rings in the three structures discussed here.

Similar consideration<sup>31</sup> was taken of the steric role of the carboxyl oxygen lone-pairs in discussing the nmr spectra of  $[\text{Co mal}_2 \text{ en}]^-$  and  $[\text{Co mal en}_2]^+$ ; there, however, the interaction of the oxygen axial lone-pairs with the orthogonally placed donor atoms of adjacent ligand

rings was also considered. For an "isolated" M-mal ring the boat and skew conformers were thought more favourable than the chair; introduction of donor nitrogens or oxygens (with their attendant amine hydrogens or oxygen lone-pairs) was considered to increase the relative favourability of the skew form. The single resonance observed<sup>31</sup> for the malonate methylene protons in the  $[\text{Co mal en}_2]^+$  ion was interpreted as indicating rapid flipping of the malonate ring between the two symmetrical skew forms ( $\lambda$  and  $\delta$ );<sup>127,128</sup> the  $[\text{Co mal}_2 \text{ en}]^-$  resonance<sup>31,32</sup> was compatible with either a two-fold symmetric bis(chair) or bis(boat) conformation but rapid conformational interchange was again thought likely. In the two independent crystal structures containing  $[\text{Co mal}_2 \text{ en}]^-$  the complex ion maintains an approximate non-crystallographic two-fold symmetry, although the malonate ring conformations are distinctly different, as indicated above.

CHAPTER 3 THE STRUCTURE OF POTASSIUM CALCIUM (+)<sub>589</sub>-TRIS(DITHIO-OXALATO)  
COBALTATE(III) TETRAHYDRATE

K.Ca(+)<sub>589</sub>[Co thiox<sub>3</sub>].4H<sub>2</sub>O, CADCOTHIOX.

3.1 STRUCTURE ABSTRACT

The crystal structure of K.Ca(+)<sub>589</sub>[Co(S<sub>2</sub>C<sub>2</sub>O<sub>2</sub>)<sub>3</sub>].4H<sub>2</sub>O has been solved and refined by full-matrix least-squares to convergence with  $R_1 = 0.062$ ; the  $\Lambda$  configuration previously assigned to the (+)<sub>589</sub>[Co thiox<sub>3</sub>]<sup>3-</sup> anion on the basis of circular dichroism correlations is confirmed by the present refinement. Structure solution was based on 2374 equi-inclination counter data recorded with *CuK $\alpha$ /Ni $\beta$*  radiation. The structure is orthorhombic,  $P_{2_1^2_1^2_1}$  (No. 19),  $a = 12.381$  (5),  $b = 12.791$  (5),  $c = 11.801$  (5) Å,  $U = 1869$  (2) Å<sup>3</sup>,  $Z = 4$ ,  $D_c = 2.03$ ,  $D_m = 2.01$  g. cm<sup>-3</sup>. Although the angles, S-Co-S, subtended at the Co atom by the three thio-oxalate ligands are close to 90° (Av.  $89.7 \pm 0.15^\circ$ ) the CoS<sub>6</sub> first coordination sphere lacks O<sub>h</sub> symmetry showing significant elongation along the pseudo-C<sub>3</sub> axis of the complex ion. The cations and water molecules make numerous close contacts with each other and with the complex anion.

3.2 EXPERIMENTAL

The complex ion was prepared and resolved following the literature procedure<sup>129</sup> except that Ca<sup>++</sup>, rather than Ba<sup>++</sup>, was chosen as the co-crystallizing cation with K<sup>+</sup> in order to reduce the scattering from atoms external to the complex ion (atomic number of calcium = 20,

barium = 56). In view of the subsequent difficulty in distinguishing the three metal atoms in the preliminary Patterson and Fourier maps ( $Z_K = 19$ ,  $Z_{Co} = 27$ ) the presence of a dominant barium ion would have been an advantage in choosing a correct starting model.

Dithio-oxalic acid from Eastman-Kodak Co., Rochester, N.Y., U.S.A..  
The resolving agent,  $(+)[Co en_2(NO_2)_2]Br$  from F.R. Keene.

Recrystallization of  $K.Ca(+)[Co thiox_3]$  from aqueous solution gave burgundy coloured rectangular prisms of the tetrahydrate, elongated along  $c^*$  and bearing  $(1,1,1)$  and  $(\bar{1},\bar{1},1)$  bevels at one end in most cases; the faces parallel to the needle axis were of the form  $\{1,1,0\}$ . Absorption and ORD spectra suggested the first coordination sphere contained some sulphur atoms and stability of the complex ion in light and its failure to racemize at a perceptible rate in aqueous solution pointed to all three ligands being bidentate through sulphur donor atoms.

Preliminary photographic investigation of several crystals revealed that twinning parallel to the  $c^*$  axis was a serious problem and although crystals suitable for integrated photographs could be readily found, there were few which met the more rigorous requirements of a diffractometer study. The films showed the space group to be  $P_{2_1^2_1^2_1}$  with  $a = 12.33$ ,  $b = 12.74$ ,  $c = 11.77 \text{ \AA}$  ( $\lambda_{CuK\alpha} = 1.5424 \text{ \AA}$ ); non-integrated Weissenberg equi-inclination films were recorded for reciprocal lattice levels up all three axes to facilitate setting of the diffractometer for recording the individual layers. Two crystals (coated with a thin film of Canada Balsam to reduce possible dehydration), one mounted about  $c^*$

and the other about  $\alpha^*$ , were used to determine more accurate lattice constants on a semi-automated Buerger-Supper Equi-inclination X-ray diffractometer using a pinhole collimator. The lattice repeats were calculated from the  $\alpha_1$  component of high order zero layer reflections using non-monochromated  $CuK\alpha/Ni f$  radiation ( $\lambda_{K\alpha_1} = 1.54051 \text{ \AA}$ ).

*Crystal data* - as in structure abstract.

$K_2Ca(+)[Co(S_2C_2O_2)_3] \cdot 4H_2O$ ;  $M = 570.6$ ;  $\mu_{CuK\alpha} = 175 \text{ cm}^{-1}$ .

$D_m$  by flotation in 1,2-dibromopropane/1,2-dibromoethane at  $23^\circ C$ .

*Microanalysis - calc.* C 12.63, S 33.71, H 1.42,  $H_2O$  12.63.

*found* 12.40, 33.4, 1.32, 11.3 (by weight loss).

$[\alpha]_{589}^{28} = +1042^\circ$ ,  $[M]_{589} = +6680^\circ$  (ref. 129,  $[M] = +5000^\circ$  for K.Ba salt).

Details of the diffractometer data collection routine and subsequent data reduction process are given in Appendix III. Using the  $c^*$  mounted crystal, reflections for layers  $l = 0 \rightarrow 9$  were measured along lines of constant  $k$ , varying  $h$  through + and - values within a machine limited  $\epsilon$  range of  $\gamma = 10-140^\circ$ ; the equi-inclination angle for layer  $hk\theta$  was  $36.03^\circ$ . With  $CuK\alpha$  radiation, the pronounced anomalous dispersion effect for this crystal reduces the symmetry of the reciprocal lattice from the Laue symmetry  $mmm$  to the point symmetry  $222$  resulting in non-equivalent  $\bar{h}k\bar{l}$  and  $\bar{h}kl$  octants; structure refinement based on this non-averaged data set was expected to yield the absolute configuration of the complex ion directly.

The  $a^*$  mounted crystal was used to generate reciprocal layers  $0kl \rightarrow 8kl$ , measuring the +++ octant only (along lines of constant  $l$  index). The  $\mu$  angle for  $8kl$  was  $29.89^\circ$ . This crystal was smaller than that used to generate the  $c^*$  data and consequently measurement of individual layers was somewhat slower; since two octants of  $c^*$  data had been recorded one octant of  $a^*$  data was adequate to achieve correct interlayer scaling of the anomalous dispersion data.

### 3.3 STRUCTURE SOLUTION AND REFINEMENT

Lorentz and polarization (but not absorption) corrections were applied to the raw reflection intensities (see Appendix III) and the three octants merged to give a unique data set of 1548 reflections having all indices positive. Although the first Patterson map based on this incorrectly averaged data showed two peaks at approximately  $2.3 \text{ \AA}$  from the origin, consistent with an approximately octahedral  $\text{CoS}_6$  coordination sphere, the number of heavy atoms per asymmetric unit (Co,  $Z = 27$ ; Ca,  $Z = 20$ ; K,  $Z = 19$ ; six S,  $Z = 16$ ) rendered location of the metal atoms uncertain; the problem is ideally suited to solution by direct methods. There were numerous peaks on the Harker ( $\frac{1}{2}$ ) sections and inclusion of a Co atom at several of the possible solutions for these vector sets gave  $R_1$  ca. 0.67 compared with a random value of 0.83: however, further structural features could not be determined from the resultant Fourier maps even though the face-centred subcell pattern of the Patterson map suggested a precise positioning of the

calcium and potassium ions relative to the oriented  $\text{CoS}_6$  core.

The structure was solved by making use of the intensity differences (Bijvoet differences) between Friedel pair reflections due to the anomalous scattering by the heavy atoms. All three metal atoms have  $\Delta f''_{\text{CuK}\alpha} > 1.0$  and  $\Delta f''$  for sulphur is 0.6 but the Co coefficient is dominant (3.9) and a Patterson map based on the Bijvoet differences between the  $^+hkl$  and  $^-hkl$   $c^*$  axis data could be expected to show a dominant peak on each Harker section corresponding to the Co-Co vectors in  $P_{2_1^2_1 2_1^2_1}$ . When comparing Friedel pairs rigorous absorption corrections should be applied<sup>44b</sup> but since the " $c^*$  crystal" was approximately uniform, other than for the bevels at one end, these corrections were not applied; comparison of some  $^+hko$  and  $^-hko$  pairs indicates this approximation is not entirely satisfactory. Data for which only one reflection of a Friedel pair was observed were prematurely excluded from the data set; this was invalid since such data, especially at high  $\sin\theta$ ,<sup>44b,130b,131</sup> can be expected to be most sensitive to anomalous dispersion, but fortunately this omission did not prevent the finding of a unique solution for the Co atom.

The  $+++$  and  $-++$   $c^*$  axis data sets comprised ca. 1200 reflections each. Two anomalous Patterson syntheses were computed,

- (a) one based on  $|\Delta F|^2 = |\bar{F} - \frac{+}{F}|^2$  for all data showing any difference in intensity of the Friedel pairs, 851  $|\Delta F|^2$  output,
- (b) and the other based on  $\Delta I = (\bar{I} - \frac{+}{I})$  where  $|\Delta I| > (\sigma_{\frac{+}{I}} + \sigma_{\bar{I}})$ ,  
417 data output:

an analogous significance test should have been applied in case (a). Reflections having at least one index zero were automatically excluded from the data set. Synthesis (a) is the "anomalous squared synthesis"<sup>130a,b</sup> and (b) a modification of the "anomalous difference Patterson" proposed by Okaya and Pepinsky.<sup>44b,130b</sup> In the ideal case synthesis (a) is more direct showing only the Harker peaks for the anomalous scatterer whereas (b) also gives peaks due to interaction of the anomalous scatterer with the normal scatterers. Interactions involving normal scatterers only should be absent from both maps.

Although the disposition of peaks was similar in the two maps there were some differences in relative peak heights. Interpretation of the dominant peaks on the Harker (1/2) sections gave a starting position for Co at ( $\pm 0.078$ , 0,  $\pm 0.213$ ). A structure factor calculation with Co at (0.078, 0, 0.213) had  $R_1 = 0.675$  and suggested further improvement was possible with lowering of the scale and isotropic temperature factors. A Fourier map phased by this model showed the expected mirror symmetry about the  $xz$  plane, but no further atomic positions could be decided. A  $\beta$ -anomalous synthesis<sup>130a</sup> computed using the 417 signed  $\Delta I$  values with Co at (0.078, 0, 0.213) yielded six possible sulphur atom sites, five of which were consistent with the strong 2.3 Å peaks in the original Patterson map. Inclusion of these six atoms in a subsequent calculation lowered  $R_1$  to 0.512 but it was not possible to locate the Ca and K atoms with certainty in the resulting Fourier.

Comparing the original Patterson map with the anomalous squared synthesis, the Ca-Ca and K-K vectors in the latter should be considerably reduced in peak height compared with those in the former, taking the Co-Co Harker peaks as reference. Two such sets of vectors were found and deconvolution gave two possible starting positions for Ca and K at (0.078, 0.440, -0.207) and (0.070, -0.280, -0.075). Inclusion of the Ca in the above model gave  $R_1 = 0.478$ ; the alternate structure with the mirror image set of sulphur atoms gave  $R_1 = 0.503$ . Positional refinement of this limited eight-atom model lowered  $R_1$  to 0.305 for the 1548 unique data. A difference map computed at this stage confirmed the K position and introduction of this atom together with four carbonyl oxygens further reduced  $R_1$  to 0.250. The two remaining carbonyl oxygens, the six ligand carbon atoms and the four water oxygens were located in the subsequent difference and Fourier maps.  $R_1$  dropped to 0.190 on inclusion of these additional atoms. Positional and isotropic refinement of all twenty-five atoms gave  $R_1 = 0.133$  ( $R_2 = 0.123$  using individual weights based on counting statistics - see Appendix III). The isotropic temperature factor for  $K^+$  was approximately three times those of Co and  $Ca^{++}$  consistent with the large spread of electron density at this site in both the difference and Fourier maps. These maps indicated that the thermal vibration of all atoms was significantly anisotropic.

There is no point in making a full anisotropic refinement of a model for a structure having a large linear absorption coefficient unless absorption corrections are first applied to the intensity data;

otherwise the temperature factors correct for this systematic error by adjusting to smaller values, generally with the complication of non-positive definite anisotropic thermal ellipsoids.<sup>45</sup> The raw data were checked for counting and punching errors before application of absorption corrections. Both crystals were described as regular parallelepipeds of square cross section neglecting the (1,1,1) and ( $\bar{1},\bar{1},1$ ) bevels and the slight inequality of the edge lengths perpendicular to the needle axis. The crystals were measured on a travelling microscope calibrated in 0.001 mm. — the  $c^*$  crystal was 0.128 x 0.146 in section and 0.321 in overall length; the effective length was considered to be less due to the angular truncations and it was described as being 0.137 x 0.137 x 0.283 mm. having a volume of  $5.296 \times 10^{-6} \text{ cm}^{-3}$ . The  $a^*$  needle was 0.134 x 0.125 in section and 0.214 in maximum length; for the purpose of applying absorption corrections it was described as 0.129 x 0.129 x 0.182 mm., having an effective volume of  $3.044 \times 10^{-6} \text{ cm}^{-3}$ . A more rigorous description of the crystal shapes may have facilitated improved fitting of the refined model to the intensity data.

Comparison of observed/unobserved reflections in the  $a^*$  set with those in the  $+++$  and  $-++$   $c^*$  octants indicated that the  $a^*$  data corresponded to the  $+++$   $c^*$  octant. Interlayer scaling of the absorption corrected  $a^*$  data with the two  $c^*$  octants separately, confirmed this assignment. The  $-++$   $c^*$  data were introduced with scale factors derived in the interlayer scaling of the  $+++$  data; the unique

data set comprised 2374  $hkl$  and  $\bar{h}k\bar{l}$  reflections. Introduction of the absorption corrected data to the structure refinement reduced the esd's of the positional coordinates and increased the isotropic temperature factors.<sup>45</sup> The large temperature factor for  $K^+$  was disturbing but attempts to represent the broad Fourier and difference peak at this site by several atoms having fractional multipliers gave no significant improvement in the least-squares agreement factors<sup>55</sup> or in the esd's of the coordinates. The isotropic stage of refinement was concluded with  $R_1 = 0.109$ ,  $R_2 = 0.100$ ,  $G = 2.862$  for the  $\Lambda$  configuration of the complex ion ( $Co^{+1}$ ,  $Ca^{+2}$ ,  $K^{+1}$  scattering anomalously — details of scattering factors used in this structure are summarized in Appendix IV, note 1),  $n = 101$ . The  $\Delta$  configuration gave  $R_1 = 0.148$  confirming that the correct absolute configuration can be derived from Patterson functions based on the Friedel pair intensity differences.

Anisotropic thermal parameters were introduced in stages; anisotropic refinement of Co, Ca, K ( $n = 116$ ) gave  $R_1 = 0.090$ ,  $R_2 = 0.079$ . Introduction of anisotropic thermal parameters for the six sulphur atoms lowered  $R_1$  to 0.073 and  $R_2$  to 0.063,  $G = 1.849$  ( $n = 146$ ). An attempted anisotropic refinement of all light atoms was unsuccessful at this stage due to non-positive definite temperature factors for several atoms of one thio-oxalate ligand. The distribution of  $Av. w\Delta^2$  versus  $|F_o|$  indicated relative over-weighting of the more intense reflections; the low angle,  $(\sin\theta)/\lambda < 0.2$ , reflections showed little evidence of an extinction effect and the few reflections affected were excluded from

subsequent least-squares cycles. Initially reflections having  $I \leq 2\sigma_I$  were excluded from the data set — of 3652  $c^*$  data 848 were unobserved, of 1532  $a^*$  data 416 were unobserved on this  $2\sigma_I$  criterion. Examination of  $|F_o|$  and  $|F_c|$  indicated that many of the weakest intensity reflections had  $|F_o| > |F_c|$ , a phenomenon usually seen with "unobserved" reflections in film data. A  $3\sigma_I$  cut-off was imposed<sup>97,132</sup> and all reflections having  $2\sigma_I < I \leq 3\sigma_I$  were retained in the data set as "unobserved" but were excluded from subsequent least-squares refinement cycles — 3920 data condensed to a unique  $hkl/\bar{h}kl$  set of 2374, of which 2086 were included in the least-squares cycles.

The anomalous scattering contribution was included for the six sulphur atoms (as well as Co, Ca, K) and the whole structure refined anisotropically (alternate cycles refining the positions,  $n = 76$ , and temperature factors,  $n = 151$ ) to convergence with  $R_1 = 0.062$ ,  $R_2 = 0.060$ ,  $G = 1.753$  ( $n = 76$ ),  $G = 1.785$  ( $n = 151$ ) in two complete cycles. The anisotropic temperature factors for atoms  $C_5$  and  $C_6$  remained non-positive definite, probably reflecting inadequate absorption correction of the intensity data.<sup>45</sup> The distribution of  $Av. w\Delta^2$  vs  $|F_o|$  was satisfactory except in the high intensity ranges and neither a Hughes<sup>133</sup> nor a Cruickshank<sup>44a</sup> weighting scheme promised any improvement; time did not permit the application of an arbitrary weighting scheme to the raw data. As indicated in Appendix III, the standard deviation assigned to the raw peak intensity is the minimum value determined by the counting statistics; in program AULAC some account is taken of the agreement of

the symmetry equivalent reflections such that  $\sigma$  for a multiply observed reflection is most commonly less than that of a "once only" observation of comparable intensity. Many of the weaker reflections were not observed in the  $\alpha^*$  data set and as "once only" observations carry a relatively high standard deviation. Coupled with the already over-optimistic  $\sigma$  values assigned to the most intense-data from counting statistics this results in a relative over-weighting of the most intense data. An additional error should be included<sup>45</sup> in  $\sigma$  to correctly represent the random errors not represented by the counting statistics.

A final difference map showed no further peaks of any significance, the minor peaks which did occur being close to supplied atom sites. The hydrogen atoms of the four water molecules could not be located. Their non-inclusion in the model and the unsatisfactory representation of the  $K^+$  disorder can also be expected<sup>44a</sup> to influence the trend in  $Av. w\Delta^2$ . Derivation of the estimated standard deviations of the variable parameters is formally invalid for weighting schemes showing this increasing trend in  $Av. w\Delta^2$  to high  $|F_o|$ ; the effect is most noticeable in the esd's of the thermal parameters.<sup>44a</sup>

$|F_o|$  and  $|F_c|$ , both  $\times 10$ , are listed in Table 3.1.

#### 3.4 STRUCTURE FIGURES AND TABLES

The figures and tables of structural parameters presented in this section are discussed in section 3.5.

are represented as spheres of fixed radius; their final anisotropic temperature coefficients are, however, listed in Table 3.2.

### 3.5 DESCRIPTION OF STRUCTURE AND DISCUSSION

The  $(+)_{589}[\text{Co thiox}_3]^{3-}$  ion has the  $\Lambda$  configuration predicted from solution CD correlations.<sup>27,134</sup> In space group  $P_{2_1^2_1^2_1}$  the complex ion possesses no crystallographic symmetry, showing small distortions from an idealized  $D_3$  (32) geometry. The atom labelling is given in Figures 3.1 and 3.2 which show the oxygen and sulphur environments of the  $\text{K}^+$  and  $\text{Ca}^{+2}$  cations; the pseudo- $C_3$  axis of the complex ion is approximately parallel to the  $b$  crystallographic axis and one of the pseudo- $C_2$  axes is approximately parallel to the  $a$  axis. The sub-cell pattern observed in the original Patterson synthesis is immediately understandable in terms of the similarity of the Co, Ca and K coordinates (Table 3.2) and the orientation of the complex ion relative to the unit cell axes (Figures 3.1 and 3.2).

Both cations make several close contacts with the more electro-negative oxygen and sulphur atoms. The  $\text{Ca}^{+2}$  is surrounded by an almost spherical arrangement of nine oxygen atoms (Table 3.7): ionic radius  $\text{Ca}^{++}$ , 0.99 Å,<sup>80</sup> oxygen van der Waals radius, 1.40 Å.<sup>80</sup> The sulphur-oxygen environment of  $\text{K}^+$  forms a cylinder of density approximately parallel to  $a$  suggesting an explanation for the large thermal anisotropy of the potassium ion in this direction (Table 3.11): ionic radius  $\text{K}^+$ , 1.33 Å,<sup>80</sup> van der Waals radius of sulphur, 1.85 Å.<sup>80</sup> From the earliest Fourier and difference maps the so-called  $\text{K}^+$  ion had always occurred

as a strong peak extended parallel to  $a$  and of integrated density equivalent to that of the more compact  $\text{Ca}^{++}$  site. Attempts to refine fractional atoms at sites slightly displaced in  $x$  only resulted in further splitting of the peak density in the difference maps and produced impossibly short close contacts with the sulphur-oxygen environment. Since both the  $\text{Ca}^{++}$  and  $\text{K}^+$  ions have an effective "atomic" number of 18 they occur with similar integrated peak densities in the Fourier maps; the above positional assignment was based on comparison of the observed close contacts with the van der Waals radii sums. Although some of the contact distances listed in Table 3.7 are too long to realistically suggest interactions of any strength it can be seen that most of the  $\text{Ca}^{++} \dots \text{O}$  close contacts are incompatible with the placing of a larger radius  $\text{K}^+$  ion at this site.

The hydrogen atoms of the four water molecules were not located in the final difference synthesis which, however, showed numerous peaks at possible suitable positions. It is probable that further significant improvement of the refined model would be achieved if these atoms were located and the thermal anisotropy (and/or splitting) of the  $\text{K}^+$  ion more correctly represented, even without modification of the data weighting.<sup>44a</sup> Several of the contacts listed in Tables 3.8 and 3.9 can not be regarded as significant in terms of the van der Waals radii sums and are included only for completeness since the large vdW radius of sulphur ( $1.85 \text{ \AA}$ ) necessitates the specification of a larger than usual contact distance. Also, it should be remembered (section 1.5) that limiting contacts  $0.3 \text{ \AA}$

less than the vdW radius sum are not uncommon.<sup>82,84</sup>

No structures having coordinated thio-oxalate ligands have hitherto been reported. The mean  $\text{Co}^{\text{III}}\text{-S}$  bond length found here (2.244 (5) Å) is shorter than that reported for most tris (four-membered ring) complexes, e.g.  $\text{Co}(\text{dte})_3$ , 2.258 (3) Å,<sup>135</sup> 2.260 (3) Å;<sup>136</sup>  $\text{Co}(\text{exan})_3$ , 2.276 (4) Å;<sup>137</sup>  $\text{Co}(\text{mtp})_3$ , 2.322 (3) Å;<sup>138</sup>  $\text{Co}(\text{xan})_3$ , 2.398 (4) Å.<sup>139</sup> Details of the complex ion geometry are given in Tables 3.3-3.6. The unsatisfactory thermal refinement of atoms  $\text{C}_5$  and  $\text{C}_6$  (represented as isotropic circles in Figures 3.1 and 3.2) results in S-C and C-C bond lengths for ligand 3 which deviate significantly from the respective means obtained for ligands 1 and 2 only; the C=O bond lengths seem less affected. These mean bond lengths for ligands 1 and 2 are S-C 1.710 (8) Å, C-C 1.516 (23) Å, C=O 1.226 (8) Å; the respective means for ligand 3 are 1.665 (7) Å, 1.603 (16) Å and 1.226 (10) Å. The mean sulphur-carbon bond length is significantly shortened from a paraffinic single bond length (1.82 Å<sup>74,116</sup>); the sum of the Pauling covalent radii<sup>140</sup> for C-S is 1.812 Å and for C=S 1.607 Å. The carbonyl bond length is not significantly different from the average (1.245 (53) Å) found<sup>87</sup> for the poorly refined  $[\text{Co ox}_3]^{3-}$  ion in KNIPHECOOX (Chapter 4); the increased ligand bite of thiox (3.16 Å) compared with ox (2.58 Å)<sup>87</sup> reflects the increased C-S bond length (1.73 Å for a shortened partial double bond<sup>74</sup>) relative to a similarly shortened C-O bond (1.36 Å<sup>74</sup>).

The bond angle errors for  $[\text{Co ox}_3]^{3-}$  are so large, except for angles at the metal, that comparison with CADCOTHIOX is not justified. The

ligand angle, O-Co-O, in  $\text{Co}(\text{ox})_3^{3-}$  was found to be  $84.3 (1.5)^\circ$ ; the mean intraligand S-Co-S angle for  $\text{Co}(\text{thiox})_3^{3-}$  is  $89.68 (19)^\circ$ . However, both complex ions are distorted toward a trigonal-prismatic ( $D_{3h}$ ) geometry such that the interligand plane dihedral angles ( $\gamma$ ) are more nearly  $120^\circ$  than is the case in octahedral geometry ( $\gamma = 90^\circ$ ). In  $\text{Co}(\text{thiox})_3^{3-}$  the six atom ligand planes are more closely parallel to the pseudo- $C_3$  axis (mean  $\gamma = 97.7^\circ$ ) than are the Co, S, S planes (mean  $\gamma = 93.0 (6)^\circ$ ); for  $\text{Co}(\text{ox})_3^{3-}$  the dihedral angles between the six atom ligand planes only were calculated but the Co and oxygen donor atoms are only slightly displaced from this mean plane ( $\gamma = 92.0^\circ$ ). Geometric distortion of tris-complex ions from an idealized geometry having an orthogonal arrangement of chelate rings is further discussed in sections 8.2 and 8.3.

Although the thio-oxalate ligands are essentially planar (Table 3.4) the displacement of the Co atom from the mean planes induces some torsion in the chelate rings, the magnitude of the torsion angles in general increasing with increasing displacement of the Co atom (Tables 3.5, 3.6). The direction of this torsion is such as to make the C-C bond of each ligand more nearly parallel to the pseudo- $C_3$  axis of the complex ion and a small relative twist of the two halves of each thiox ligand about its C-C bond is observed (insignificant for ligand 2).

The esd's in the bond lengths and angles for this structure are a significant improvement over those of NADCOMALEN and CRMALTCOPN; this is particularly true of the angles subtended by the ligands at the metal

atoms — in NADCOMALEN,  $\sigma$  for these three angles averaged  $0.90^\circ$ , in CRMALTCOPN where the metal atoms occupy special positions the average  $\sigma$  was  $0.75^\circ$ , and here  $0.15^\circ$ . It is this angle ( $\alpha$ ) and its related angles which are important in the evaluation of the distortion model of optical activity as it applies to chiral trigonal-dihedral transition metal complexes. Although some of the improvement in the average  $\sigma$  can be attributed to the presence of heavier atoms, i.e. sulphur, in the first coordination sphere of  $[\text{Co thiox}_3]^{3-}$  it is due largely to having an excess of accurate counter data. It is probable that a more correct representation of the random errors in the data set by the weighting scheme and a more rigorous application of absorption corrections (either through a more realistic description of the crystal morphology or empirically<sup>44b</sup> by making use of the observed differences in the intensities of zero-layer Friedel pairs) would further reduce the estimated standard deviations of the positional and thermal parameters, and hence of the derived bond lengths and angles. In view of this improvement in  $\sigma$  a more complete data set (especially for  $hkl$ ,  $l = 2n + 1$  should be obtained on a diffractometer for the CRMALTCOPN structure.

Some miscellaneous notes on refinement details and data presentation for the three structures NADCOMALEN, CRMALTCOPN and CADCOTHIOX are collected together as Appendix IV.

CHAPTER 4 THE ABSOLUTE CONFIGURATION OFPOTASSIUM (+)<sub>589</sub>-TRIS(1,10-PHENANTHROLINE)NICKEL(II)-(-)<sub>589</sub>-TRIS(OXALATO)COBALTATE(III) DIHYDRATE.K(+)<sub>589</sub>[Ni phen<sub>3</sub>]<sub>(-)</sub><sub>589</sub>[Co ox<sub>3</sub>].2H<sub>2</sub>O, KNIPHECOOX.4.1 INTRODUCTION

In 1968 the structure of the title salt was solved and refined by full-matrix least-squares using *MoK $\alpha$ /Zrf* integrated precession intensities;  $R_1 = 0.126$ ,  $R_2 = 0.108$ . However, an attempt to determine the absolute configuration of the structure using *CuK $\alpha$ /Ni $\beta$*  integrated precession data was unsuccessful. The absolute configurations of the complex ions were successfully determined in mid 1969 using non-integrated *CuK $\alpha$ /Ni $\beta$*  Weissenberg data, visually estimated against the calibration strip used for the NADCOMALEN anomalous data. Although the full structure refinement is in print (ref. 87) the derivation of the complex ion configurations was presented as a summary without listing the Friedel pairs; these data are given in full here.

4.2 DETERMINATION OF THE CONFIGURATION

Several well formed crystals of K(-)[Ni phen<sub>3</sub>](+)[Co ox<sub>3</sub>].2H<sub>2</sub>O were grown by interfacial growth over periods of 24 hours from cooled aqueous acetone solutions of the two components: details concerning the ensuring of the optical purity of these crystals are given elsewhere.<sup>87</sup> One such crystal was used to generate the *hk1* and *hk3* reciprocal layers. The equi-inclination angle,  $\mu$ , for each layer was offset by ca.

0.5° to minimize possible multiple reflection effects.<sup>141-143</sup> Because the  $00l$  reflection, where  $l = 2n + 1$ , is systematically absent the odd level data should be less susceptible to multiple reflection disturbance than the even order layers. An automatic liquid nitrogen cold temperature attachment was developed for use in this work to increase the quality of the anomalous diffraction data consequent on the reduced thermal vibration, but the device has not been tested sufficiently to permit details to be given here.

The visually estimated data were scaled approximately against the *Mo* microdensitometer data before comparison with the calculated structure factors based on the  $K(+)[Ni\ phen_3](-)[Co\ ox_3].2H_2O$  structure having both complex ions in a  $\Lambda$  absolute configuration. Absorption corrections were not applied. From an inspection of Table 4.1 it can be seen that most reflections designated "unobserved" have appreciable  $|F_c|$  values while some having  $|F_c| < 100$  occur with measurable intensity. Others, e.g. (2,11,3) and (4,3,3), exhibit insignificant differences between the calculated structure factors of the  $\bar{k}$  and  $\bar{k}$  reflections.

Three structure factor calculations were made with

- (i)  $Co^{+2}$  scattering anomalously,  $\Delta f''_{Co} = 3.87$ ;
- (ii)  $Co^{+2}$  and  $Ni^0$  scattering anomalously,  $\Delta f''_{Ni} = 0.60$ ;
- (iii)  $Co^{+2}$ ,  $Ni^{+1}$ ,  $K^{+1}$  scattering anomalously,  $\Delta f''_K = 1.10$ .

Details of the scattering factor curves are given in Appendix IV, note 1. All three calculations confirmed the  $\Lambda$  absolute configuration for both  $(+)[Ni\ phen_3]^{2+}$  and  $(-)[Co\ ox_3]^{3-}$ . Of the 33 unique pairs the number

a. symmetry equivalent to an  $hk1$  reflection.

b.  $|F_O|, |F_c| \times 10$ .

c. (2,4,3) and (4,3,3) contradict the  $\Lambda$  assignment in all three calcs.

d. (2,11,3) inverted in relative  $|F_c|$  values in calculation (iii).

favouring this assignment were (i) 31, (ii) 31 and (iii) 30. In calculations (i) and (ii) the *Mo* scattering curve was mistakenly used for  $\text{Ni}^{\text{O}}$  rather than the *Cu* curve (for *MoK $\alpha$* ,  $\Delta f'_{\text{Ni}} = 0.4$ ; for *CuK $\alpha$* ,  $\Delta f'_{\text{Ni}} = -3.1$ ) but this error will not affect the relative ordering of the  $|F_c|$ 's within a Friedel pair; it can affect the magnitude of the difference between the two  $|F_c|$  values. Calculations (i) and (ii) were closely similar. Introduction of  $\Delta f''_{\text{K}}$  in calculation (iii) together with use of the correct scattering curve for Ni with *CuK $\alpha$*  radiation gave some appreciable changes in  $F_c$  (apart from the change in scale of some data), e.g. the pair (2,4,3) became identical in  $|F_c|$  and (2,11,3) which had previously calculated the same became unequal for the  $\bar{k}$  and  $\bar{k}$  reflections.

Thus, even for this inadequately refined structure<sup>87</sup> (no anisotropic refinement, water molecules not located) comparison of Friedel pair intensities gives a quite definite indication of the absolute configuration. It has been noted elsewhere<sup>144</sup> that this method of determining absolute configuration is not limited to accurately refined structures whereas comparison of  $R_1$  values for the two enantiomers may not give a significant indication.

CHAPTER 5 ABSOLUTE CONFIGURATIONS BY CORRELATION5.1 INTRODUCTION

The powder method of X-ray crystallography can be used to assign the absolute configuration of a molecule or ion of unknown chirality by correlation with a related molecule of known configuration. The success of the technique relies on a qualitative comparison of the spacing and relative intensities of the diffraction lines produced by a microcrystalline specimen having only one hand of the "unknown" molecule in the crystal lattice with the diffraction pattern obtained from the reference powder.

Two approaches have previously been used. In cases where racemization in solution is slow and completely resolved samples of the relevant ions (or molecules) can be readily prepared the method of active racemates<sup>145,146</sup> has been successfully applied, e.g. to the tris-(diamines) of trivalent transition metals.<sup>147</sup> The rationale is as follows: for a molecule with optical antipodes  $(+)\alpha$  and  $(-)\alpha$  the crystal structure of the racemate  $(+)\alpha(-)\alpha$  is necessarily different from that of the pure enantiomers. Similarly for  $(+)\beta$  and  $(-)\beta$ . In certain cases, however, where the heavy atoms dominate the scattering, the diffraction patterns of the enantiomers and the racemate may appear qualitatively similar.<sup>147</sup> If  $\beta$  is stereochemically similar to  $\alpha$  (i.e. of the same size, shape and ionic charge, such as  $\text{Co}(\text{en})_3^{3+}$  and  $\text{Cr}(\text{en})_3^{3+}$ ) an active racemate can be formed. If, for example,  $(+)\alpha$  and  $(+)\beta$  co-crystallize and the resulting crystals  $(+)\alpha(+)\beta$  give a powder

pattern identical with that of  $(+)\alpha(-)\alpha$ , then  $(-)\alpha$  and  $(+)\beta$  have the same absolute configuration. The absolute configuration of  $(+)\beta$  is thus determined if that of  $(-)\alpha$  is known. Co-crystallization of  $(+)\alpha$  with  $(-)\beta$  would give crystals isostructural with the pure antipodes but correlation via these latter crystals is unacceptable since the  $(+)\alpha/(-)\beta$  mixture could equally well consist of discrete  $(+)\alpha$  and  $(-)\beta$  crystals.

A second approach, which is more generally applicable (i.e. can be used where racemization in solution is too rapid to permit complete resolution of the antipodes) but at the same time less rigorous, is to compare the powder pattern of the less-soluble diastereoisomer formed between the molecule of unknown chirality and its resolving agent with that of the reference molecule resolved in the same way; this method is an extension of Werner's least-soluble diastereoisomer approach.<sup>148,149</sup> It is necessary to have a resolving agent of high purity which precipitates one hand of the resolvable complex to the almost total exclusion of the other. Having established the isomorphism of the unknown and reference diastereoisomers it remains only to identify the precipitated chiral molecule.

There are two potential sources of error in this method. In many cases the less-soluble diastereoisomer is only sparingly soluble in neutral solution and any attempt at further purification of the resolved complex by fractional recrystallization normally results in appreciable racemization. It is therefore more convenient to determine the optical

sign of the complex present in the diastereoisomer by measuring the optical rotation of the solution remaining after precipitation. Excess resolving agent must be removed from the filtrate to prevent a false indication of resolution and in the present work this was achieved by ion exchange. The success of this operation can be checked by recording the optical rotatory dispersion (ORD) curve for the filtrate throughout the accessible wavelength range, since for the ionic complexes considered here the ORD curve is a good "fingerprint" of the  $ML_6$  chromophore.

The other source of error lies in the degree of specificity of the resolving agent for one hand of the chiral complex. Where discrimination between the two enantiomers is absolute, i.e. no precipitation of one hand even at very high concentration, there can be no doubt as to the assignment. In many systems, however, a change of conditions<sup>150</sup> (e.g. solvent, concentration, temperature) can induce precipitation of either hand of the chiral molecule, e.g. strychnine +  $Cr(ox)_3^{3-}$  (ref. 27);  $M(en)_3^{3+}$  with  $M(ox)_3^{3-}$  where  $M = Co, Cr,$  and  $Co(thiox)_3^{3-}$  (this work and refs. 129 and 150).

Consider the system  $(\pm)\alpha$  with resolving agent  $R$ ; if  $R$  precipitates both  $(+)\alpha$  and  $(-)\alpha$  as discrete crystals, i.e.  $R(+)\alpha$  and  $R(-)\alpha$ , in approximately equal proportions then the resulting powder pattern will be a composite of the two diastereoisomer patterns. One set of experimental conditions may precipitate  $R(+)\alpha$  in slight excess, say 10%, of  $R(-)\alpha$ ; the filtrate would show a negative residual rotation but the powder pattern would be that of the  $R(+)\alpha/R(-)\alpha$  mixture. A slightly different set of

conditions could give  $R(-)\alpha$  in 10% excess over  $R(+)\alpha$ ; this time the residual rotation of the filtrate would be positive but again the powder pattern would be that of the mixture. Although the relative line intensities would be slightly different for the two mixtures a qualitative examination of line positions would reveal them to be identical and the non-sensical conclusion could be drawn that  $(+)\alpha$  and  $(-)\alpha$  have the same absolute configuration. Here the fallacy in the argument is obvious because the resolving agent has been shown to precipitate appreciable proportions of both enantiomers, but where the comparison is being made between two related systems  $\alpha$  and  $\beta$ , treated independently with resolving agent R, precautions must be taken to exclude the possibility of erroneous comparison of diastereoisomer mixtures, i.e.  $R(+)\alpha/R(-)\alpha$  with  $R(+)\beta/R(-)\beta$ . This difficulty can be averted if pure samples of the reference enantiomer,  $(+)\beta$  and  $(-)\beta$ , are available since powder patterns of the pure diastereoisomers  $R(+)\beta$  and  $R(-)\beta$  can then be generated for comparison.

This chapter summarizes the preparation and attempted resolution of several complexes related to the four structures reported in Chapters 1-4. In the discussion section the absolute configurations determined during the course of this work, i.e. Chapters 1-5, are compared with the configurations previously assigned on the basis of published CD and ORD curves.

5.2 EXPERIMENTAL(1) MO<sub>6</sub> Chromophores.i. oxalates:

$K_3[Co\ ox_3].3H_2O$ <sup>151</sup> and  $K_3[Fe\ ox_3].xH_2O$ <sup>152</sup> were prepared by literature methods. Attempted resolution of the ferric complex ion and a student preparation of  $K_3[Al\ ox_3].3H_2O$ <sup>151</sup> with (+)[Ni phen<sub>3</sub>]<sup>2+</sup> and (+)[Co en<sub>3</sub>]<sup>3+</sup> was unsuccessful. Resolution<sup>153</sup> of  $K_3[Co\ ox_3].3H_2O$  and  $K_3[Cr\ ox_3].3H_2O$ <sup>151</sup> (supplied by Dr. M.R. Snow) with (+)[Ni phen<sub>3</sub>]<sup>2+</sup> gave (+)Ni(-)Co and (+)Ni(+)Cr as the less-soluble diastereoisomers; powder photographs showed these to be isomorphous.

Exclusive precipitation of the (+)Ni(-)Co isomer has been demonstrated elsewhere.<sup>87</sup> Thus (+)[Cr ox<sub>3</sub>]<sup>3-</sup> has the  $\Lambda$  configuration previously determined for (-)[Co ox<sub>3</sub>]<sup>3-</sup>, (see Chapter 4). Precipitation of these two anions as salts of (+)[Co en<sub>3</sub>]<sup>3+</sup> and (-)[Co(-)pn<sub>3</sub>]<sup>3+</sup> resulted in the formation of both possible diastereoisomers (this work and ref. 150), the one forming to excess depending on the conditions of resolution.

ii. malonates:

a)  $K_3[Co\ mal_3].4H_2O$  was prepared by the method of Kneten and Spees;<sup>154</sup> other reported methods<sup>103</sup> require more rigorous control of pH. The emerald green needles of the racemate (turquoise by transmitted light) were characterized by determination of the lattice constants from  $MoK\alpha/Zr\ f$  ( $\lambda = 0.7107\ \text{\AA}$ ) precession photographs -

$K_3[Co(C_3H_2O_4)_3].4H_2O$ ;  $M = 547.5$ ; orthorhombic,  $P_{na2_1}$  (No. 33);  
 $a = 21.32$ ,  $b = 12.07$ ,  $c = 14.05\ \text{\AA}$ ,  $U = 3617\ \text{\AA}^3$ ,  $D_m = 2.00_7\ \text{gm. cm}^{-3}$

(by flotation in 1,2-dibromopropane and 1,2-dibromoethane at 23°C),  $Z = 8$ ,  $D_c = 2.01$ .

The solution absorption spectrum was identical with that of Kneten and Spees.<sup>154</sup> Ion exchange chromatography indicated the presence of two components, a narrow faint green band moving even more slowly than the major emerald green  $\text{Co}(\text{mal})_3^{3-}$  species. Aqueous solutions become pale pink on standing, the rate of decolouration being accelerated by light; a similar but slower colour change occurs in the solid state and probably indicates decomposition to Co(II) malonate and bis(malonato) species analogous to the solid state deterioration<sup>155</sup> of  $\text{K}_3[\text{Co ox}_3] \cdot 3\text{H}_2\text{O}$  on prolonged exposure to sunlight.

Resolution as the least soluble  $(-)[\text{Co}(-)\text{pn}_3]^{3+}$  diastereoisomer precipitated the  $(-)_600 \text{Co}(\text{mal})_3^{3-}$  enantiomer. The powder pattern was identical with that of  $(-)[\text{Co}(-)\text{pn}_3](+)[\text{Cr mal}_3] \cdot 3\text{H}_2\text{O}$ . Extreme insolubility of the  $\text{Co}(\text{pn})_3 \cdot \text{M}(\text{mal})_3$  salts and very high solubility of the tris-(malonato) ions in water render further purification by fractional crystallization difficult. Optical purity of the precipitated diastereoisomers is suggested by the following points:

- using a slight excess, e.g. 1.1:2, of resolving agent to racemate for the initial precipitation resulted in a residual green filtrate from which no precipitation could be induced by the further addition of a large excess (5x) of  $(-)[\text{Co}(-)\text{pn}_3] \cdot \text{Br}_3$ ;
- microscope examination of several batches of diastereoisomer crystals revealed only the trigonal-prismatic morphology and all single crystals of  $(-)[\text{Co}(-)\text{pn}_3](+)[\text{Cr mal}_3]$  examined gave X-ray diffraction patterns

consistent with the space group  $R_{32}$  (see Chapter 2).

The purity of the less-soluble diastereoisomers could be tested by calculation of the powder pattern corresponding to the known  $(-)[Co(-)pn_3](+)[Cr\ mal_3]\cdot 3H_2O$  structure; a crystalline impurity present at levels exceeding 5% should be distinguishable.

The identical powder patterns suggest that  $(-)_600[Co\ mal_3]^{3-}$  has a  $\Lambda$  configuration: this enantiomer has a weak negative rotation at 589 nm.

b) Ni(II) malonate<sup>156</sup> and  $K[Cr\ mal_2(H_2O)_2]^{102,157}$  were prepared by published methods with the intention of determining the conformations of the malonate ligands and the absolute configuration of the chiral forms of the latter complex ion. However, attempts to grow suitable crystals of the former complex were unsuccessful and this work was not pursued when it became apparent (Chapters 1 and 2) that the conformation of the chelated malonate ligand was determined as much by crystal packing and intermolecular hydrogen bonding as by intra-molecular steric interactions.

### iii. carbonate and succinates:

The tris(carbonato)Co(III) ion was prepared in aqueous solution<sup>158-160</sup> and resolution of the emerald green complex ion attempted using  $(+)Co(en)_3^{3+}$ ; a green-brown precipitate formed immediately but the residual filtrate was inactive. Attempted resolutions with  $(+)Ni(phen)_3^{2+}$ ,  $(-)Co(-)pn_3^{3+}$  and precipitation with  $Co(tn)_3^{3+}$  were also unsuccessful.

Attempted preparation of  $K_3[Cr\ succ_3]$  by Chang's method<sup>102</sup> for preparing the tris(malonato) complex was not successful; the failure of this method had been previously reported by Lapraik.<sup>101</sup> Attempts to prepare  $K_3[Co\ succ_3]$  by oxidation of Co(II) or from the reaction of succinic acid with an aqueous suspension of  $Na_3[Co(CO_3)_3]$ , methods successfully employed in the synthesis of tris(malonato)- and tris(oxalato)Co(III) complexes, were not successful.

(2) MN<sub>6</sub> Chromophores.

i. 2,4-diaminopentane.<sup>†1</sup>

Dippel and Jaeger<sup>161</sup> successfully synthesized several bis- and tris-transition metal complexes of the *meso* and *racemic* forms of 2,4-diaminopentane: some resolutions were achieved and the conformational specificity of the chelated ligands resulting from the two exocyclic methyl groups indicated. More recent preparations<sup>38,162</sup> follow the original method<sup>163</sup> of reduction of acetylacetonedioxime with ethanolic sodium, but with some modification of the isomer purification and resolution procedures.

Failure of the *racemic* and *meso*-dihydrochlorides to give sharp melting points<sup>38,162,163</sup> necessitated characterization by NMR spectroscopy.<sup>162</sup> We were unable to readily monitor the successive stages of fractional crystallization by this method and it was decided to attempt separation of the isomers by fractional crystallization of the di-nitric acid salts

<sup>†1</sup> Preparation of this ligand undertaken with R.J. Geue.

which had reported<sup>163,164</sup> melting points of 165-169°C and 195-196°C for the  $\alpha$ - and  $\beta$ - isomers respectively. Dippel<sup>164</sup> separated the *meso* and *racemic* isomers as the diacetyl derivatives claiming resolution of the  $\beta$ -form (therefore *racemic*) with (+)-tartaric acid; he was unable to resolve the  $\alpha$ -isomer by any method. On repeating this method of separation it has been concluded<sup>38,162</sup> on the basis of the NMR spectra and resolution properties that the  $\alpha$ -form of Dippel corresponds to the pure *racemic* isomer whereas the  $\beta$ -form was an ca. 30:70 mixture of *racemic* and *meso*.

Fractional recrystallization of the dinitric acid salts (from aqueous ethanol) provided a further check of Dippel's assignment. The recrystallization cycle resulted in a low melting (m.pt. 165°C) and a high melting fraction (m.pt. 195-6°C) in good agreement with the literature values. The 60 MHz NMR spectrum of the high melting fraction in D<sub>2</sub>O was qualitatively identical with that reported<sup>162</sup> for the *meso*-dihydrochloride; the  $\beta$ -form of Dippel is therefore the *meso*-isomer. The NMR spectrum of the low melting fraction was a composite of the published *meso*- and *racemic*-dihydrochloride spectra. The high melting  $\beta$  fraction was less soluble in aqueous ethanol than the 165°C  $\alpha$  fraction: Appleton and Hall<sup>162</sup> found the converse for the *meso*- and *racemic*-dihydrochloride salts.

Inability to purify the racemic ligand<sup>165</sup> and the successively decreasing yields obtained throughout the preparative sequence discouraged further work on this system, especially when it was learnt<sup>39,40</sup> that the structures of the relevant tris-cobalt complexes were already being studied.

ii. 1,3-diaminopropane complexes:

$[\text{Co}(\text{tn})_3]\text{Cl}_3$  was prepared by the method of Jonasson et al,<sup>166</sup> but using a 20% excess of ligand.  $[\text{Cr}(\text{tn})_3]\text{Cl}_3$  was synthesized by refluxing a dimethyl sulphoxide solution of anhydrous chromic chloride<sup>67,167</sup> with tn in the presence of a granule of zinc.<sup>168</sup> Both complexes were resolved using  $(-)\text{K}[\text{As}(\text{cat})_3]$ ,<sup>37</sup> ( $[\alpha]_D^{22} = -527^\circ$ , prepared by M.R. Snow by the published method<sup>169</sup>), added in a molar ratio Co:As = 2:3. Diastereoisomer crystals were obtained from 50% aqueous-acetone solutions after standing for several days; too rapid precipitation gave no apparent resolution.

Solubility of the diastereoisomers in acidified aqueous-acetone with attendant destruction of the resolving agent permits determination of the ORD curve both for the cation present in the crystals and that remaining unprecipitated in the supernatant. For  $\text{Co}(\text{tn})_3^{3+}$  the (+) enantiomer always crystallized to excess; however, with  $\text{Cr}(\text{tn})_3^{3+}$  both possible diastereoisomers were obtained, the precise conditions determining the one forming to excess. Growing the crystals from aqueous-acetone in a desiccator containing anhydrous calcium chloride, conditions favouring more rapid loss of water than acetone, precipitated  $(-)_400 \text{ Cr}(-)\text{As}$  to excess; growth from identical solutions in an open beaker at  $-5^\circ\text{C}$ , conditions favouring faster loss of acetone, precipitated  $(+)_400 \text{ Cr}(-)\text{As}$  to excess. Attempted purification of the antipodes of  $\text{Cr}(\text{tn})_3^{3+}$  by fractional crystallization was unsuccessful.

The  $(+)\text{Co}(-)\text{As}$  powder specimen decomposed too rapidly in the X-ray beam to permit the recording of a sufficiently intense powder photograph.

Instead, low angle ( $2\theta = 4-25^\circ$ ) powder diffractometer traces were run for the three diastereoisomers. The positions and relative intensities of the dominant peaks (set A) were identical in the (+)Co(-)As and (+)<sub>400</sub> Cr(-)As traces; the (-)<sub>400</sub> Cr(-)As trace also showed these peaks (A) but at reduced intensity relative to the most dominant peaks (set B). The strongest B peaks were discernible in the (+)Co(-)As and (+)<sub>400</sub> Cr(-)As traces but with intensities much reduced relative to the A peaks. Although none of the diastereoisomers is optically pure it seems probable that the A lines are characteristic of the (+)Co(-)As and (+)<sub>400</sub> Cr(-)As diastereoisomers; on this basis (+)<sub>400</sub>[Cr tn<sub>3</sub>]<sup>3+</sup> is assigned the same absolute configuration as (+)[Co tn<sub>3</sub>]<sup>3+</sup>, namely  $\Delta$ .

A more thorough characterization of this system is desirable.

### (3) Phenanthrolines, Dipyridyls.

The tris(phen) and tris(dipy) complexes of Ni(II),<sup>170,171</sup> Fe(II)<sup>172</sup> and Ru(II)<sup>173-175</sup> were prepared by published methods. Ni(phen)<sub>3</sub><sup>2+</sup> was resolved as the (+) antimony-tartrate<sup>170,176</sup> and both antipodes purified by fractional recrystallization from aqueous-acetone as the perchlorates ( $[\alpha]_{589}^{25} = -1448^\circ, +1387^\circ$ ); precipitation studies confirmed the exclusive precipitation of (+)Ni(phen)<sub>3</sub><sup>2+</sup> as the less-soluble antimony(+)-tartrate. The three diastereoisomers (+)Ni-, (+)Ru- and (-)Fe(+)-antimonytartrate gave identical powder diffraction photographs; thus (+)[Ru phen<sub>3</sub>]<sup>2+</sup> and (-)[Fe phen<sub>3</sub>]<sup>2+</sup> have the  $\Lambda$  absolute configuration determined for (+)[Ni phen<sub>3</sub>]<sup>2+</sup>, (Chapter 4).

Attempted resolution of the tris(dipy) complexes using potassium(+)-

antimony tartrate, potassium(+)tartrate,  $(-)\text{Co}(\text{ox})_3^{3-}$  and  $(-)\text{As}(\text{cat})_3^-$  was not successful.

(4) Technical Details.

Resins used in the ion exchange columns for removal of excess resolving agent were: anion, Bio-Rad AG1-X4; cation, Dowex 50W/X4.

Powder photographs of the diastereoisomers were recorded using  $\text{CuK}\alpha/\text{Ni}\beta$  radiation and a small radius ( $r = 28.65$  mm.) Nonius general purpose camera; background fogging of the films due to fluorescent scatter from Co derivatives was reduced by placing a dummy film in front of the intensity recording film. Diffraction line positions and relative intensities were compared qualitatively without determination of  $d$  spacings. Powder diffractometer traces were recorded with monochromatic  $\text{CuK}\alpha$  radiation in the range  $4^\circ \leq 2\theta \leq 25^\circ$  on a Philips Geiger Counter X-ray Spectrometer at a scan speed of  $0.5 \text{ deg. min}^{-1}$  with a slit width of 0.5 degrees.

Qualitative solution absorption spectra were determined using a Perkin-Elmer 402 Ultraviolet-Visible Spectrophotometer. The solution ORD curves of Figures 5.1 and 5.2 were measured manually on a Perkin-Elmer Model 141MC Spectropolarimeter having a quartz-iodine cycle tungsten lamp as illuminating source. The detector was an RCA IP28A photomultiplier. The specified spectral range of this machine is 250-650 nm; the spectral range of the lamp is quoted as 350-650 nm (continuous) and the photomultiplier has a specified response range of ca. 300-700 nm. Most

solutions, however, gave measurable optical activity at wavelengths greater than 700 nm and it has been suggested<sup>177,178</sup> that the apparent rotation in this region is the result of higher frequency radiation passing the grating monochromator. The glass sample cell is opaque at wavelengths less than ca. 330 nm. Attempts to measure the ORD curves of solids on this machine were unsuccessful.

ORD and CD curves of the microcrystalline solids and CD curves of the optical enantiomers were recorded by Dr. M.R. Snow at Northwestern University, Evanston, using a Cary Model 60 Circular Dichrograph. All chemical samples were forwarded from Adelaide and in the case of the more labile complexes, resolutions were repeated at Evanston to permit recording of the solution CD spectra. The microcrystalline samples were measured as KBr discs (ca. 5% of diastereoisomer); single crystal specimens could not be measured.

The CD and ORD curves which follow are qualitative representations only; the ordinate is arbitrary in all but Figures 5.1 and 5.2; all curves are plotted against wavelength in nanometres.

### 5.3 DISCUSSION

Some reference to Chapter 6 may be helpful in reading this discussion section.

#### 5.3.1 ORD and CD Curves

Published solution CD curves, or summaries of their characteristic

features, are available for the  $\text{Co/Cr}(\text{tn})_3^{3+}$ ,  $\text{Ni/Ru/Fe}(\text{phen})_3^{2+}$ ,  $\text{Co/Cr}(\text{ox})_3^{3-}$ ,  $\text{Cr}(\text{mal})_3^{3-}$ ,  $\text{Co}(\text{thiox})_3^{3-}$  and  $\text{Co}(\text{mal})_2(\text{en})^-$  complex ions (see section 5.3.2); solution ORD curves are now rarely published and have been located only for the former five systems.<sup>30,60,99,150,179</sup> Previous attempts<sup>154</sup> to resolve  $[\text{Co mal}_3]^{3-}$  have been unsuccessful and the features of its ORD and CD spectra are here compared with those of related  $\text{CoO}_6$  and  $\text{CrO}_6$  chromophores; the peak, trough and null positions of the CD spectra of the tris(oxalato)- and tris(malonato)-complexes of Co and Cr are summarised in Table 5.1.  $[\text{Co mal}_3]^{3-}$  was recently resolved<sup>180,181</sup> as the (+)  $\text{Co}(\text{en})_3^{3+}$  diastereoisomer and the observed solution CD spectrum is in agreement with that of Figure 5.3(c); however, the CD components could not be assigned.

The broad qualitative similarity of the solution ORD curves of  $\Delta\text{-Co}(\text{ox})_3/(\text{mal})_3$  and  $\Delta\text{-Cr}(\text{ox})_3/(\text{mal})_3$  shown in Figures 5.1 and 5.2 suggests that the shape of the rotatory dispersion curve is characteristic of the  $\text{ML}_6$ -chromophore and the absolute configuration of the complex ion and largely independent of the chelate ring size and possible conformer lability. The published<sup>60</sup> ORD spectra of  $\Lambda(+)\text{Cr}(\text{en})_3^{3+}$  and  $\Lambda(-)\text{Cr}(\text{tn})_3^{3+}$  are also similar in shape; however, the ORD curve<sup>60</sup> of  $\Lambda(-)\text{Co}(\text{tn})_3^{3+}$  exhibits only the short wavelength features of the  $\Lambda(+)\text{Co}(\text{en})_3^{3+}$  spectrum. This correspondence between the ORD curves of the five- and six-membered ring complexes confirms the  $\Lambda$  absolute configuration assigned to  $(-)\text{Cr}(\text{tn})_3^{3+}$ ,  $(+)\text{Cr}(\text{mal})_3^{3-}$  and  $(-)\text{Co}(\text{mal})_3^{3-}$ . A ring size effect<sup>25</sup> observed in the  $\text{Co}(\text{en})_3/(\text{tn})_3$  system, i.e. reduced rotatory strength with increasing chelate ring size, is also found for the

b. this work.

$M(\text{ox})_3/(\text{mal})_3$  system. Only  $\text{Cr}(\text{ox})_3^{3-}$  racemized appreciably during the time taken to manually scan the spectra of Figures 5.1 and 5.2 (see the experimental points 1, 2, 3 on Figure 5.1).

The visible absorption maxima of the  $\text{Co}(\text{ox})_3/(\text{mal})_3$  and  $\text{Cr}(\text{ox})_3/(\text{mal})_3$  systems correspond almost exactly: peak positions, with  $\epsilon_{\text{max}}$  in parentheses are  $\text{Co}(\text{ox})_3^{3-}$  602 nm (153), 422 (204),<sup>27</sup> for  $\text{Co}(\text{mal})_3^{3-}$  607.5 (148), 423.5 (127),<sup>154</sup> for  $\text{Cr}(\text{ox})_3^{3-}$  571 (74), 422 (97)<sup>27</sup> and for  $\text{Cr}(\text{mal})_3^{3-}$  575 (30), 428 (24).<sup>27</sup> For the tris(oxalato) complexes the high energy  $d-d$  transition has the greater electric-dipole strength but this situation is reversed in the tris(malonates). The absorption spectra of Figures 5.3(a) and 5.4(a) were determined qualitatively for the samples used in determining the ORD and CD spectra of those figures.

The ORD and CD spectra of Figures 5.3, 5.4, 5.5 and 5.6 were measured on the Cary Model 60 Circular Dichrograph. The (-)  $\text{Cr}(\text{mal})_3^{3-}$  solution ORD curve (5.4(b)) is identical with that of Figure 5.2; the (+)  $\text{Co}(\text{mal})_3^{3-}$  curve (5.3(b)), however, has not been recorded to sufficiently high wavelength since it is still increasing, in violation of the Drude equation.<sup>8</sup> A similar criticism can be made of the (-)  $\text{Cr}(\text{mal})_3^{3-}$  curve of Figure 5.2 although in that case the effect is most probably due to higher frequency "stray" light — it is not possible on the available evidence to decide the correct long wavelength termination of the manual ORD curves.

ORD spectra of the microcrystalline less-soluble diastereoisomers diluted in pressed KBr discs give no readily interpretable information. However, some features of the CD spectrum of such a matrix are of interest

when compared with the CD spectra of the isolated optically active components of the diastereoisomer. Before discussing the curves of Figures 5.3(c) and 5.4(c) some observations on the (+)  $\text{Co(en)}_3^{3+}$ - $\text{Co/Cr(ox)}_3^{3-}$  CD spectra represented in Figures 5.5 and 5.6 are warranted.

- a) The CD spectra of  $\Lambda(-)$   $\text{Co(ox)}_3^{3-}$  and  $\Lambda(+)$   $\text{Co(en)}_3^{3+}$  are unaltered by pressing in a potassium bromide disc.
- b) The spectra (Figure 5.5) are qualitatively similar; the dominant CD peak is positive in both curves and occurs at 493 nm for (+)  $\text{Co(en)}_3^{3+}$  and 617 nm for (-)  $\text{Co(ox)}_3^{3-}$ . This relative displacement of the major CD maxima corresponds with a shift of the  ${}^1A_{1g} \rightarrow {}^1T_{1g}$  transition from 469 nm in  $\text{Co(en)}_3^{3+}$  to 602 nm in  $\text{Co(ox)}_3^{3-}$ .
- c) Comparison of the composite curve (Figure 5.6) with the KBr disc spectrum of (+)[Co en<sub>3</sub>]<sup>-</sup>[-Co ox<sub>3</sub>] (precipitated from a mixture of the pure optical enantiomers;  $[\alpha]_D^{22}$  (+)[Co en<sub>3</sub>]Cl<sub>3</sub>.3H<sub>2</sub>O = 148°, (-)K<sub>3</sub>[Co ox<sub>3</sub>].3H<sub>2</sub>O = -2300°) indicates that the latter is not simply a 1:1 summation of the component spectra. There is, however, some correspondence of peak and trough positions although there is obviously an additional long wavelength trough ( $\lambda$  ca. 650 nm) in the diastereoisomer CD spectrum.

The crystal structure of  $\Lambda(+)$ [Co en<sub>3</sub>] $\Lambda(-)$ [Co ox<sub>3</sub>] is not known (see subsequent comments on the  $\Delta(-)$ [Co(-)pn<sub>3</sub>] $\Lambda$ [M mal<sub>3</sub>] diastereoisomer CD spectrum). The (+)[Co en<sub>3</sub>](+)[Cr ox<sub>3</sub>] CD spectrum is included in Figure 5.6 for comparison.

The positions and relative magnitudes of the observed maxima and

minima in the (-)  $\text{Cr}(\text{mal})_3^{3-}$  aqueous solution CD spectrum (Table 5.1) correspond closely with those published by McCaffery et al.<sup>27</sup> Further, these CD peaks and troughs occur at wavelengths similar to those of the observed inflexion points in the solution ORD curves. Despite the expected complication of overlapping dispersion curves arising from adjacent optically active transitions, similar close correspondence occurs between the CD and ORD curves of other chiral transition metal complexes, e.g. (+)  $\text{Cr}(\text{en})_3^{3+}$ , (+)  $\text{Cr}(\text{tn})_3^{3+}$ , (ref. 60), and more particularly here for (-)  $\text{Co}(\text{ox})_3^{3-}$  and (+)  $_{600}\text{Co}(\text{mal})_3^{3-}$ . Mathematical deconvolution of a complex ORD curve into the contributions from the individual transitions is a distinct possibility<sup>71,183</sup> if the frequency interval of the optically active transitions is known.

(-)  $\text{Co}(-)\text{pn}_3^{3+}$  gives absorption peaks at 468 nm ( $\epsilon_{\text{max}} = 96$ ) and 340 nm (90).<sup>27</sup> Its CD curve is similar to the inverse of that shown (Figure 5.5) for (+)  $\text{Co}(\text{en})_3^{3+}$  with some change in relative peak heights; published<sup>27</sup>  $(\epsilon_L - \epsilon_R)_{\text{max}}$  values for the two complex ions are —

(-) $\text{Co}(-)\text{pn}_3^{3+}$	493 nm (-1.95),	439 (+0.58),	348 (-0.20)
(+) $\text{Co}(\text{en})_3^{3+}$	493 nm (+1.89),	428 (-0.17),	351 (+0.25).

The rotatory strengths of the  $d-d$  transitions of  $\text{Cr}(\text{mal})_3^{3-}$  are an order of magnitude less than those of the five-membered ring tris(diamine) and tris(oxalato) complexes in line with the reduced electric-dipole strengths of the electronic transitions. The literature<sup>27</sup> values of  $(\epsilon_L - \epsilon_R)_{\text{max}}$  for the (-)  $\text{Cr}(\text{mal})_3^{3-}$  ion in aqueous solution are —

620 nm (+0.07),	555 (-0.20),	420 (+0.04);
-----------------	--------------	--------------

these values are  $\frac{1}{2}$  to  $\frac{2}{3}$  of the values given in Table 5.1 but this is of

no significance to the following discussion. A further small negative peak,  $(\epsilon_L - \epsilon_R)_{max}$  ca. -0.02 on the scale of the literature data, was found at 372 nm (Table 5.1).

The major interest lies in the  $(-)[Co(-)pn_3](+)[Cr\ mal_3]$  diastereoisomer curve (Figure 5.4(c)); if this curve were merely a 1:1 superposition of the CD spectra of the component enantiomers then, neglecting probable peak overlap, the succession of peaks (relative heights and assignments from literature) to decreasing wavelength should be

$E_a\ mal$	$A_2\ mal$	$E_a\ pn$	$A_2\ pn$
620 nm (-3.5),	555 (+10),	493 (-97.5),	439 (+29),
$E_b\ mal$	? $mal$	$E_b\ pn$	
420 (-2),	372 (+1),	348 (-10).	

The diastereoisomer KBr disc CD spectrum bears little resemblance to this composite pattern, providing further evidence that the optical activity profile of a solid diastereoisomer is not simply the superposition of its component spectra. Assignment of transitions to the peaks of the  $(-)[Co(-)pn_3](+)[Cr\ mal_3]$  CD spectrum is therefore somewhat tenuous. The structure is known (Chapter 2) and the trigonal  $R_{32}$  space group makes this an ideal case for the measurement of single-crystal solid state spectra provided large crystals can be grown.

Regrettably absorption spectra of the diastereoisomers pressed as KBr discs were not recorded; hence it is not known if the  $d-d$  transitions in the diastereoisomer are appreciably shifted from their positions in the component spectra. However, some comment is possible.

- a) In the  $(-)$   $\text{Cr}(\text{mal})_3^{3-}$  solution spectrum two CD peaks occur under the short wavelength absorption band and for  $(+)$   ${}_{600}\text{Co}(\text{mal})_3^{3-}$  there are three. Three weak CD peaks are also observed in this region in the solution CD spectrum of  $(-)$   $\text{Co}(\text{ox})_3^{3-}$  (Figure 5.5) and have been quoted<sup>27,184</sup> as evidence of lower symmetry species, e.g.  $[\text{Co ox}_2(\text{H}_2\text{O})_2]^-$ . This interpretation has been questioned<sup>185,186</sup> and in the present work ion exchange chromatography of a sample of  $\text{K}_3[\text{Co ox}_3]$  showed only one slow moving band. A similar explanation is possible for the three high energy components in the  $(+)$   $\text{Co}(\text{mal})_3^{3-}$  CD spectrum but ion exchange showed the concentration of species other than the triply negative tris-(malonato) ion to be negligible<sup>187</sup> —N.B. this does not exclude the possibility of a triply charged dimeric species.

Contributions from different conformers can also be postulated in the six-membered ring systems. Although the structure refinement (Chapter 2) indicates the presence of orientational disorder in the  $\Delta(-)[\text{Co}(-)\text{pn}_3]\Lambda(+)[\text{Cr mal}_3]\cdot 3\text{H}_2\text{O}$  lattice no evidence was found in the difference maps for malonate species other than the particular flattened conformer indicated in Figure 2.1. Even so, the complex ion need not be three-fold symmetric but simply three-fold disordered. The solid state conformation implies nothing about the conformational lability of  $\text{Cr}(\text{mal})_3^{3-}$  in solution.

- b) The CRMALTCOPN structure showed the complex ions to be strongly

hydrogen bonded parallel to their  $C_3$  axes (Figure 2.3). This hydrogen bonding scheme seemingly induces appreciable distortion of both the cation and anion (see Tables 8.1, 8.6) in excess of that predicted on the basis of the electrostatic repulsion model outlined in section 8.2. The observed enhancement of the  $A_2$  component rotatory strength relative to that of  $E_\alpha$  in the aqueous solution CD spectrum of  $\text{Co(en)}_3/(\text{pn})_3^{3+}$  on the addition of tetrahedral oxyanions (e.g. phosphate, selenite - see section 8.3) has been rationalized<sup>67,188,189</sup> in terms of hydrogen bonding of the anion to the trigonal nitrogen faces of the cation. On this basis the  $(-)[\text{Co}(-)\text{pn}_3](+)[\text{Cr mal}_3]$  diastereoisomer peaks at 505 nm (-) and 450 nm (+) can be interpreted as deriving predominantly from the  $E_\alpha \text{ pn}$  and  $A_2 \text{ pn}$  components.

A similar explanation could be proposed for the dominant negative peak at ca. 590 nm, namely as being due to enhancement of  $E_\alpha \text{ mal}$  at the expense of  $A_2 \text{ mal}$ , analogous to the situation observed<sup>60,67,189,190</sup> for  $\text{Co}(\text{tn})_3^{3+}/\text{PO}_4^{3-}$  on the most recent assignment<sup>36</sup> of trigonal components. No change was observed in the aqueous solution spectra of  $(-)\text{Cr}(\text{mal})_3^{3-}$  or  $(+)\text{Co}(\text{mal})_3^{3-}$  on the addition of ammonium ions (as  $\text{NH}_4\text{Cl}$ ) which it might have been thought would hydrogen bond to the carboxyl-oxygen lone-pairs in an orientation similar to that proposed for the binding of  $\text{PO}_4^{3-}$  to the trigonal faces of the  $\text{Co}(\text{en})_3^{3+}$  ion. This experiment was not tried for the

tris-oxalate ions.

The (+)[Co en<sub>3</sub>](−)[Co ox<sub>3</sub>] diastereoisomer is a  $\Lambda\Lambda$  arrangement and the crystal structure will be different from that of CRMALTCOPN which is  $\Delta\Lambda$ . Even so the diastereoisomer CD spectrum shows increased rotatory strength in the region of the  $A_2$  en component relative to that at the wavelength of the  $E_\alpha$  en component (Figures 5.5 and 5.6). Accurate structure determinations of both this and the  $\Delta$ [Co en<sub>3</sub>] $\Lambda$ [Co ox<sub>3</sub>] diastereoisomer would be invaluable, as would the KBr disc spectrum of the  $\Delta\Lambda$  structure.

- c) (+) Cr(mal)<sub>3</sub><sup>3−</sup> and (−)<sub>600</sub> Co(mal)<sub>3</sub><sup>3−</sup> have a  $\Lambda$  absolute configuration. The microcrystalline KBr disc spectra of their (−) Co(−)pn<sub>3</sub><sup>3+</sup> diastereoisomers are closely similar for  $\lambda > 400$  nm (Figures 5.3(c) and 5.4(c)); both exhibit enhancement of the 450 nm (+) component relative to the 505 nm (−) peak of the cation. The diminished rotatory strength in the 540–400 nm region relative to the strong negative peak at ca. 600 nm is more pronounced for the Co(mal)<sub>3</sub><sup>3−</sup> diastereoisomer reflecting the greater dipole and rotatory strengths of the long wavelength transition of this anion compared with that of Cr(mal)<sub>3</sub><sup>3−</sup>. It seems probable that this dominant negative component in the two diastereoisomer spectra has the same origin and can be assigned  $E_\alpha$  mal by correlation with the polarized crystal assignment<sup>29</sup> for Cr(mal)<sub>3</sub><sup>3−</sup> in a (NH<sub>4</sub>)<sub>3</sub>[Fe mal<sub>3</sub>] host lattice.

The aqueous solution CD spectra of (−) Cr(mal)<sub>3</sub><sup>3−</sup> and

(+)  ${}_{600} \text{Co}(\text{mal})_3^{3-}$  under the envelope of the short wavelength (ca. 420 nm) absorption band are similar with an additional minor trough in the (+)  $\text{Co}(\text{mal})_3$  spectrum at 460 nm appearing as a shoulder in the (-)  $\text{Cr}(\text{mal})_3$  curve. A major difference occurs under the low energy band envelope; apart from the presence of a small maximum at ca. 670 nm in the (-) Cr spectrum, the sign ordering of the two major components is reversed. The literature component assignment for (-)  $\text{Cr}(\text{mal})_3^{3-}$  gives 620 nm  ${}^4E_\alpha$ , 555 nm  ${}^4A_1$ ; CD values have been given above.

Non-observance of the 670 nm  $\text{Co}(\text{mal})_3^{3-}$  solution peak in the KBr disc spectrum suggests that it is analogous to the ca. 550 peak of  $\text{Cr}(\text{mal})_3^{3-}$  and can hence be assigned  ${}^1A_2$  symmetry. The observed shifts in wavelength of the  $E_\alpha$  component peaks from solution to solid (620  $\rightarrow$  590 nm for  $\text{Cr}(\text{mal})_3^{3-}$ ; 593  $\rightarrow$  605 nm for  $\text{Co}(\text{mal})_3^{3-}$ ) are consistent with the postulated enhancement of the  $E_\alpha$  component rotatory strength and a concomitant reduction of the A component. The greater shift in the  $\text{Cr}(\text{mal})_3$  case is understandable in terms of a larger relative contribution from the adjacent negative  $E_\alpha$   $pn$  component compared with the situation in the  $\text{Co}(\text{mal})_3$  diastereoisomer (see ref. 187 for an alternative discussion — the long wavelength CD components could equally be interpreted in terms of a conformer equilibrium).

This postulated energy ordering of  ${}^1E_\alpha$  and  ${}^1A_2$  is

identical with that found<sup>36</sup> for  $\Delta(+)[\text{Co}(\text{tn}_3)\text{Cl}_3 \cdot 4\text{H}_2\text{O}$ ; the reversal of  $E_\alpha$  and A component energies from Cr(III) to Co(III) is in agreement with Burer's correlations.<sup>70,191</sup>

Thus, to summarize, it seems that the broad shape of the ORD curve is characteristic of the  $\text{ML}_6$ -core and the complex ion absolute configuration and in favourable instances the inflexion points correlate well with the positions of the observed CD peaks. The ion exchange experiments indicate that the multiple CD components commonly observed under the short wavelength absorption band envelope of chiral Co(III)/Cr(III) $\text{O}_6$  species do not result from low symmetry mono- and bis-complexes although triply charged dimeric species and tris-species having one "dangling" bidentate ligand are not excluded; for the tris(malonato) complexes contributions from different conformers offer a possible explanation of the solution spectra. Solid state CD spectra of microcrystalline diastereoisomers can not be regarded simply as a superposition of the spectra of the individual enantiomers; in the present work a rationalization in terms of relative enhancement and diminution of spectral components seems plausible.

Finally, in retrospect, comparison of the recorded curves would have been facilitated by accurate quantitative determination of all spectra although this is difficult for the KBr disc measurements. Replotting the curves against frequency would have permitted identification of non-Gaussian peaks and possibly given some indication of minor spectral components (though there is some question as to whether CD peaks should

be symmetrical with respect to frequency or wavelength<sup>191</sup>).

### 5.3.2 Absolute Configurations: Literature References

This section collates the absolute configuration determinations summarized in this and the preceding four chapters. Except for the tris(phen) and tris(dipy) complexes all literature predictions of absolute configuration referenced here are based on the empirical model<sup>58,192,193</sup> which assigns a  $\Lambda$  absolute configuration to complexes exhibiting a positive  $E_{\alpha}$  CD component, or  $E_{\alpha}$  derivative in cases having symmetry lower than  $C_3$ , under the envelope of the long wavelength  $T_1$  symmetric octahedral transition. The varying predictions of other models as they apply to tris-bidentate Co(III) and Cr(III) complexes are summarized in Chapter 7 and the often conflicting predictions of the " $E_{\alpha}$  sign model" and "trigonal-twist distortion model" discussed more fully in section 8.3.

The  $\Delta$  absolute configuration determined for  $(+)_{546}[\text{Co mal}_2 \text{ en}]^-$  has recently been confirmed by the independent<sup>89,90</sup> structure refinement of  $\Delta(-)[\text{Co en}_2(\text{NO}_2)_2]\Delta(+)[\text{Co mal}_2 \text{ en}]$ ; there is no sign change in the aqueous solution ORD curve of this complex anion between 546 nm and 589 nm. This assignment is in agreement with an earlier prediction<sup>30</sup> based on a comparison of the CD spectrum of  $(-)[\text{Co mal}_2 \text{ en}]^-$  with that of  $(+)_{589} \equiv (-)_{546}[\text{Co ox}_2 \text{ en}]^-$ ; both spectra exhibit a positive low-frequency peak which was assigned  $A$  symmetry and considered to derive from the  $E_{\alpha}$  component<sup>3,58</sup> of  $(+)[\text{Co en}_3]^{3+}$ .

Prolonged discussion of the CD spectra of the oxalate/en and malonate/en complexes of Co(III) is not warranted but the following correlation of

absolute configurations should be noted.  $(-)[\text{Co en}_2(\text{NO}_2)_2]^+$  precipitates<sup>72</sup>  $(+)[\text{Co mal}_2 \text{ en}]^-$  as the less-soluble diastereoisomer, both complex ions having the  $\Delta$  absolute configuration.<sup>89,93</sup>

$(-)[\text{Co en}_2(\text{NO}_2)_2]^+$  also precipitates<sup>150</sup>  $(+)[\text{Co ox en}_2]^+$ ,  $(+)_{546}[\text{Co ox}_2 \text{ en}]^-$  and  $(+)_{546}[\text{Co EDTA}]^-$ , (EDTA = ethylenediaminetetraacetate), although none of these four diastereoisomers can seriously be considered to be isostructural; indeed with a slight change of conditions  $(-)_{546}[\text{Co ox}_2 \text{ en}]^-$  precipitates to excess.<sup>72,194</sup>  $(+)_{546}[\text{Co ox}_2 \text{ en}]^-$  and  $(+)_{546}[\text{Co EDTA}]^-$  have been assigned<sup>179</sup>  $\Delta$  configurations from the correspondence of their ORD curves with that of the related stereospecifically coordinated<sup>195</sup>  $(+)_{546}[\text{Co}(-)\text{PDTA}]^-$ , (PDTA = propylenediaminetetraacetate). The similarity of the ORD curves<sup>179</sup> in the substitution sequence  $(+)[\text{Co en}_3]^{3+}$ ,  $(+)[\text{Co ox en}_2]^+$ ,  $(-)_{546}[\text{Co ox}_2 \text{ en}]^-$ ,  $(-)[\text{Co ox}_3]^{3-}$  also suggests a  $\Lambda$  configuration for these four ions; the  $\Lambda$  configuration for  $(+)[\text{Co ox en}_2]^+$  has been confirmed<sup>196</sup> by X-ray diffraction. The sequence of  $\Lambda$  absolute configurations is thus  $(-)[\text{Co ox}_3]^{3-}$ ,  $(-)_{546}[\text{Co ox}_2 \text{ en}]^-$ ,  $(+)[\text{Co ox en}_2]^+$ ,  $(+)[\text{Co en}_3]^{3+}$ ,  $(?)[\text{Co mal en}_2]^+$ ,  $(-)[\text{Co mal}_2 \text{ en}]^-$ ,  $(-)_{600}[\text{Co mal}_3]^{3-}$ .

Conflicting assignments<sup>28,197-199</sup> of the absolute configurations of transition metal phenanthroline and dipyridyl complexes have been made, opposing predictions arising from the differences in the models used to explain the observed spectral phenomena (for a concise summary see ref. 3). The CD spectra of these complexes are now generally interpreted on the basis of exciton theory and the  $\Lambda$  configuration determined (Chapter 4) for  $(+) \text{Ni}(\text{phen})_3^{2+}$  is in agreement with the more rigorous theoretical

treatments (see section 7.1). A structure determination<sup>26</sup> of the less-soluble antimony (+) tartrate diastereoisomer of (-)  $\text{Fe}(\text{phen})_3^{2+}$  confirmed the  $\Lambda$  configuration for the cation; comparison of the powder photographs of the antimony (+) tartrate salts of (+) Ni(II), (-) Fe(II) and (+) Ru(II)(phen)<sub>3</sub><sup>2+</sup> confirms the  $\Lambda$  configuration suggested for all three from qualitative comparison of their ORD<sup>150</sup> and CD spectra.<sup>21,24,199</sup> Note that although these crystalline diastereoisomers have different numbers of waters of crystallization per formula unit<sup>176,200</sup> this does not imply a structural difference since the water molecules may be randomly disordered.

Oxidation of the divalent M(II)(phen)<sub>3</sub>/(dipy)<sub>3</sub> complexes (M = Ru, Os) to the +3 state causes significant changes in the long wavelength region of the CD spectrum with only quite small changes in the ultra-violet region<sup>21,199</sup> and it is questionable whether oxidation to the trivalent state occurs with retention of configuration in the Ni(II), Fe(II), Ru(II) and Os(II) complexes; to date the absolute configuration of a trivalent complex has not been determined X-ray crystallographically. Further points of interest are the relationship of the absolute configurations of the divalent tris(phen) and tris(dipy) complexes and the elucidation of possible structural reasons for the more rapid racemization of the latter complexes relative to the M(phen)<sub>3</sub><sup>2+</sup> species.<sup>23,171,201</sup>

Use of the exciton theory is formally identical in both the M(phen)<sub>3</sub><sup>2+</sup> and M(dipy)<sub>3</sub><sup>2+</sup> complexes but early comparisons<sup>28,202</sup> were confounded by incorrect application of Werner's least-soluble

diastereoisomer criterion;<sup>148</sup> the antimony (+) tartrate derivatives have been shown not to be isomorphous.<sup>176,200,203</sup> Although Gillard et al.<sup>204</sup> have recently successfully correlated the absolute configurations of the M(II)(phen)<sub>3</sub>/(dipy)<sub>3</sub> series by synthesis of (+) Ru(dipy)<sub>3</sub><sup>2+</sup> from (+) Ru(phen)<sub>3</sub><sup>2+</sup> with retention of configuration, the paucity of structural data for these systems is disturbing. An accurate structure determination of a resolved M(dipy)<sub>3</sub><sup>2+</sup> complex is required and in view of the conflicting theoretical treatments<sup>22,24,205,206</sup> of the spectra of mixed (phen)/(dipy) complexes accurate structure determinations of these resolved species would also be of value.

[Co ox<sub>3</sub>]<sup>3-</sup> occupies a place in the CD theory of MO<sub>6</sub> chromophores as important as that of (†) Co(en)<sub>3</sub><sup>3+</sup> in relation to MN<sub>6</sub> chromophores. The  $E_\alpha$  component was assigned from a single-crystal polarized absorption spectrum<sup>207</sup> of the Co(ox)<sub>3</sub><sup>3-</sup> ion diluted in the trigonal host lattice Na.Mg[Al ox<sub>3</sub>].9H<sub>2</sub>O; the oriented single-crystal CD spectrum<sup>27,184</sup> of (-) Co(ox)<sub>3</sub><sup>3-</sup> in the same lattice showed  $E_\alpha$  to have a positive rotatory strength. Although the negative anion was assigned a  $\Lambda$  absolute configuration on this basis the interpretation remained somewhat questionable because of the appearance of three CD components under the envelope of the high energy *d-d* visible absorption band whereas only one component is predicted for D<sub>3</sub> symmetry. This assignment of a  $\Lambda$  configuration to the (-) Co(ox)<sub>3</sub><sup>3-</sup> ion was confirmed by the solution of the KNIPHECOOX structure (Chapter 4).<sup>87</sup>

(+) Cr(ox)<sub>3</sub><sup>3-</sup> and (-) Cr(mal)<sub>3</sub><sup>3-</sup> were likewise predicted<sup>27,28</sup> to have a  $\Lambda$  absolute configuration. The  $\Lambda$  configuration for the former

complex ion is confirmed by the present correlation of powder diffraction patterns. However, the crystal structure determination of CRMALTCOPN (Chapter 2)<sup>93</sup> has established a  $\Lambda$  configuration for (+)  $\text{Cr}(\text{mal})_3^{3-}$ ; the assignment of the  $E_\alpha$  component of this complex anion was based on a single-crystal polarized absorption spectrum<sup>29</sup> of  $\text{Cr}(\text{mal})_3^{3-}$  diluted in a  $(\text{NH}_4)_3[\text{Fe mal}_3]$  lattice of unknown structure (see section 8.3).

(+)  $_{546} \equiv (-) \text{Co}(\text{thiox})_3^{3-}$  has previously been assigned<sup>27,134</sup> a  $\Delta$  configuration on the basis of an observed high-energy negative  $E_\alpha$  component in the aqueous solution CD spectrum. Two independent assignments have been made; in one case<sup>134</sup> the  $E_\alpha$  component was fixed assuming enhancement<sup>191</sup> of this degenerate transition due to significant  $\pi$  back-bonding from the thiox ligand to the metal but in the other assignment<sup>27</sup> the basis for the energy ordering of the trigonal components was not indicated. These assignments of a  $\Lambda$  configuration to (+)  $\text{Co}(\text{thiox})_3^{3-}$  are confirmed by the CADCOTHIOX structure refinement (Chapter 3).

Failure to resolve the labile  $\text{Fe}(\text{ox})_3^{3-}$  and  $\text{Al}(\text{ox})_3^{3-}$  complex ions has been reported<sup>208-210</sup> previously although resolution of both has reputedly been achieved.<sup>211-213</sup>  $\text{Co}(\text{CO}_3)_3^{3-}$  has recently<sup>214</sup> been resolved by precipitation as the less soluble (+)  $\text{Co}(\text{en})_3^{3+}$  diastereoisomer. The potassium bromide disc microcrystalline CD spectrum of the  $\Lambda(+)[\text{Co en}_3](-)[\text{Co}(\text{CO}_3)_3]$  diastereoisomer exhibits a positive component at ca. 610 nm; two more peaks of similar magnitude are observed in the region of the low energy  $d-d$  transition of  $\text{Co}(\text{en})_3^{3+}$ , namely at ca.

490 nm (+) and 430 nm (-). The similar peak height of the latter two components compared with the situation observed for (+)  $\text{Co(en)}_3^{3+}$  in solution<sup>27</sup> (493 nm (+1.89), 428 nm (-0.17)) or pressed as a KBr disc<sup>215</sup> is analogous to the situation observed for both  $\Delta(-)[\text{Co}(-)\text{pn}_3]\Lambda[\text{M mal}_3]$  diastereoisomers and the  $\Delta(+)[\text{Co en}_3]\Lambda(-)[\text{Co ox}_3]$  diastereoisomer (section 5.3.1). Although the lone positive peak at 610 nm is more closely similar to the situation in the tris(malonate) diastereoisomer spectra (inverted throughout the wavelength region) suggesting a  $\Delta$  configuration for the  $(-)[\text{Co}(\text{CO}_3)_3]^{3-}$  ion, the  $(+)[\text{Co en}_3](-)[\text{Co}(\text{CO}_3)_3]^{3-}$  spectrum is not very different from the superposition of the  $\Lambda(+)\text{Co(en)}_3^{3+}/\Lambda(-)\text{Co(ox)}_3^{3-}$  solution spectra (Figure 5.6) and the literature assignment of a  $\Lambda$  configuration to  $(-)\text{Co}(\text{CO}_3)_3^{3-}$  may yet prove correct. A structure determination is required.

The absolute configuration of the cation in the  $(-)[\text{Co tn}_3]\text{Br}_3 \cdot \text{H}_2\text{O}$  crystal lattice was determined<sup>120</sup> as  $\Lambda$ . Earlier assignments<sup>191,216</sup> based on the sign of the prominent Cotton effect of the long wavelength transition<sup>60,189,190</sup> predicted the enantiomeric configuration but more recent correlations were verified, although it now seems<sup>36,96</sup> (see section 8.3) that these were founded on an erroneous interpretation of the solution CD spectrum. The solution ORD spectrum of  $(-)\text{Co}(\text{tn})_3^{3+}$  determined in the present work was identical with that of Woldbye;<sup>60</sup> the optical activity of several samples of resolved  $\text{Cr}(\text{tn})_3^{3+}$  was negligible at 589 nm but the ORD curve obtained for  $(-)_400\text{Cr}(\text{tn})_3^{3+}$  was qualitatively identical with that reported by Woldbye<sup>60</sup> for  $(-)_589\text{Cr}(\text{tn})_3^{3+}$ . Solution CD spectra of the  $\text{M}(\text{tn})_3^{3+}$  species were not redetermined and rapid deterioration of the

$[M\text{tn}_3](-)[\text{As cat}_3]$  diastereoisomer crystals on isolation from the mother liquor prevented measurement of the spectra for the microcrystalline samples. Both Woldbye<sup>60</sup> and Beddoe<sup>67,190</sup> resolved the  $M(\text{tn})_3^{3+}$  complex ions as the (+) nitro-camphorates (NCS); the less-soluble diastereoisomers were (-) Cr.NCS and (-) Co.NCS.

Diffraction patterns of the two salts were not compared but Beddoe<sup>67</sup> claimed that the similarity of the  $(-)[\text{Cr tn}_3](+)\text{NCS}$  and  $\Lambda(+)[\text{Cr en}_3](+)\text{NCS}$  powder patterns argued a  $\Lambda$  configuration for  $(-)\text{Cr}(\text{tn})_3^{3+}$ . Although this reasoning is extremely tenuous, the observation that both  $(-)\text{Co}(\text{tn})_3^{3+}$  and  $(-)\text{Cr}(\text{tn})_3^{3+}$  are precipitated as the less-soluble (+) nitro-camphorates offers further support to the tentative assignment based on comparison of the powder diffractometer traces of their  $(-)\text{As}(\text{cat})_3^-$  derivatives and the qualitative similarity of the  $(-)\text{Cr}(\text{tn})_3^{3+}$  and  $\Lambda(+)\text{Cr}(\text{en})_3^{3+}$  aqueous solution ORD spectra.

Spectral implications of the geometric distortion of the  $\text{ML}_6$ -cores of the tris(ox), tris(mal), tris(thiox) and tris(tn) complex ions, *inter alia*, are discussed in section 8.3.

*Summary list of complex ions assigned a  $\Lambda$  absolute configuration on the basis of the crystal structure determinations and powder diffraction pattern correlations in the present work.*
